Abstract

This paper analyzes multifactor models in the presence of a large number of potential observable risk factors and unobservable common and group-specific pervasive factors. We show how relevant observable factors can be found from a large given set and how to determine the number of common and group-specific unobservable factors. The method allows consistent estimation of the beta coefficients in the presence of correlations between the observable and unobservable factors. The theory and method are applied to the study of asset returns for A-shares and B-shares traded on the Shanghai and Shenzhen stock exchanges, and to the study of risk prices in the cross section of returns.

Key words: factor models, panel data analysis, penalized method, LASSO, SCAD, heterogenous coefficients

1 Introduction

The arbitrage pricing theory (APT) of Ross (1976), together with multifactor models of asset returns, plays a central role in modern finance theory. Under a multifactor model, the return of each security is expressed as a linear combination of a small number of factor returns and an asset-specific return. In the capital asset-pricing model (CAPM) of Sharpe (1964) and Lintner (1965), for example, the common factor is the market return. There is a growing body of empirical evidence that stock returns are related to factors based on macroeconomic, market- and firm-level characteristics.

Although multifactor models are widely used in practice, there is scope to develop and to implement a new model-building procedure. For example, Goyal et al. (2008) argued that the assumption that all factors influence a large number of assets, so-called pervasive factors, are too strong if an economy is partitioned into several groups. They emphasized that APT allows for the existence of common pervasive factors influencing returns of securities in all groups, and of group-specific pervasive factors affecting returns of securities only in some groups. Connor and Korajczyk (1993) pointed out that industry-specific components may not be pervasive sources of uncertainty for the entire economy. See also Cho et al. (1986) and Bekaert et al. (2009). Here, we provide three examples that illustrate the group structure in financial markets.

Example 1: A relevant instance of a group structure in financial markets is the Chinese stock market. The Chinese market is divided into two segments, namely the once-restricted A-shares and the B-shares. The A-shares were initially designated exclusively for domestic investors and are denominated in Chinese renminbi (RMB), whereas the B-shares were initially designated exclusively for foreign investors and are denominated in foreign currency. Although the launch of the qualified foreign institutional investors policy by the Chinese government allowed foreign investors to enter the domestic A-share market, currency barriers may still hinder them from investing in A-shares. The
Chinese government also decided to open the B-share market to domestic investors. There is evidence to suggest that the security returns for dual-listed shares on the Chinese A- and B-share markets are priced differently because the two markets are segmented (Ma, 1996; Su, 1999; and Fung et al., 2000).

**Example 2:** The two main stock exchanges in the United States, the New York Stock Exchange (NYSE) and the National Association of Securities Dealers Automated Quotations (NASDAQ), provide an additional instance of a grouped financial market structure. The NYSE is a specialist-based auction system, whereas the NASDAQ is a computer-based dealer market. Goyal et al. (2008) argued that “While the NYSE and NASDAQ provide the same service, their underlying structures, rules, and governing principles are very different”. Empirical evidence indicates that the securities traded on these two exchanges are different (Naranjo and Protopapadakis, 1997; Schwert, 2002; Malkiel and Xu, 2003; Baruch and Saar, 2009; Goyal et al., 2008). See also a survey paper by Karolyi and Stulz (2003).

**Example 3:** Fama and French’s (1993) three-factor model uses the portfolio returns formed by sorting stocks on total equity capitalization (size), the ratio of book value to market value of common equity (book-to-market), and the market return. Griffin (2002) reported that country-specific versions of the three-factor model were more useful in explaining stock returns than a global version of the three-factor model. Fama and French (2012) studied stock returns using size, book-to-market, and momentum factors for four regions (North America, Europe, Japan, and Asia–Pacific), considering both integrated and local models. Lewis (2011) provided a review of the current body of research addressing global asset-pricing challenges. Evidence suggests that the world stock markets may be analyzed by constructing several market groups.

There exists a literature on grouped-factor structure, for example, Diebold et al. (2008), Kose et al. (2008), Moench and Ng (2011), Moench et al. (2013), and Wang
(2010). The existing literature does not consider the joint presence of observable and unobservable factors. Little work has been done on pinpointing the differences between factor structures across groups (Goyal et al. 2008).

This paper makes both theoretical and empirical contributions to the literature on asset pricing with factor models. Theoretically, this paper develops a new multifactor pricing model with both observable and unobservable factors. The unobservable part consists of common pervasive factors that affect securities in all groups, and of group-specific pervasive factors that only affect the securities in a given group.

The number of observable risk factors can be very large. These factors may include macroeconomics variables (such as exchange rates, oil prices, and inflation rates), financial market variables (such as volatility indices, trading volumes, liquidity, and total market values), and firm-level characteristics (such as dividend yields, the cost of capital, cash-flow-to-price ratios, and book-to-market equity ratios, etc). We aim to select the relevant observable factors from a large given set. For this purpose, we use the smoothly clipped absolute deviation (SCAD) penalty approach (Fan and Li, 2001). This penalty was initially proposed in the context of cross-section regression (non panel data) without a factor structure, and under iid errors. In this paper we establish the variable-selection consistency and the large sample inferential theory for panel data models. The results are obtained under the settings that allow unobservable factors, and cross-sectional and serial dependence and heteroskedasticity in the error terms.

This paper further proposes a new measure for selecting a proper model from among many candidates, equivalently, determining the number of common/group-specific pervasive factors, and determining the magnitude of the regularization parameter for implementing the shrinkage approach. We show that the proposed criterion can identify the number of true common/group-specific pervasive factors consistently. Monte Carlo simulations confirm that the proposed multifactor-modeling procedure performs well.
Empirically, the paper applies the proposed modeling procedure to the market structure of A- and B-share markets in China. We address empirical questions such as: How many common and group-specific pervasive factors exist in the stock market in mainland China? What type of observable risk factors explains the market? And, how can the unobservable common factors be understood in terms of observable variables in the economy? For example, by identifying the common and group-specific driving forces underpinning macroeconomic variables, we can obtain a further understanding of the market structure. We find that there are, at most, two common pervasive factors across the groups and four group-specific pervasive factors, three of which belong to the B-share markets. In addition, we find that some variables from overseas economies, such as stock market returns of other countries, exchange rates, and commodity markets are related to the security returns of the A- and B-shares. Moreover, we find that some domestic macroeconomic variables are relevant risk factors.

2 Model

This paper considers a panel of asset returns with a large number of observable risk factors, a set of common pervasive factors that affect the returns of all securities in all groups, and group-specific pervasive factors that affect the returns of all securities only in a specific group.

Let \( t = 1, \ldots, T \) be the time index, \( G \) be the prespecified number of groups, \( N_1, \ldots, N_G \) be the number of securities in each group, and \( N = \sum_{g=1}^{G} N_g \) be the total number of securities. The asset return of the \( i \)-th security, \( y_{it} \), observed at time \( t \), belonging to group \( g_i \in \{1, \ldots, G\} \), is expressed as follows:

\[
y_{it} = x_{it}' \beta_i + f_{c,t}' \lambda_{c,i} + f_{g,t}' \lambda_{g,i} + \varepsilon_{i,t}, \quad i = 1, \ldots, N, \quad t = 1, \ldots, T.
\] (1)

In a vector form, the model (1) can be expressed as: \( \mathbf{y}_i = \mathbf{X}_i \beta_i + \mathbf{F}_c \lambda_{c,i} + \mathbf{F}_g \lambda_{g,i} + \varepsilon_i \),
Here \( x_{it} \) is the \( p_i \times 1 \) vector of observable risk factors, and the dimension of \( x_{it} \) can be very large and may vary over \( i \). \( f_{c,t} \) is an \( r \times 1 \) vector of unobservable common pervasive factors that affect the returns of all securities in all groups, and \( f_{g_i,t} \) is an \( r_{g_i} \times 1 \) vector of unobservable group-specific pervasive factors that affect the returns of securities only in group \( g_i \). The \( p_i \times 1 \) vectors \( \beta_i \) are the unknown regression coefficients, \( \lambda_{c,i} \) and \( \lambda_{g_i,i} \) are factor loadings, and \( \varepsilon_{it} \) are the security-specific returns. Some of the observable risk factors \( x_{it} \) may be common to all firms (\( x_{it} \) does not depend on \( i \)), or common to some of the groups, or specific to a particular firm. Again, the dimension of \( x_{it} \) may be large. The heterogeneous slope coefficients in this model are in contrast to the homogeneous regression coefficients in Bai (2009) \((\beta_i = \beta)\). The heterogeneity in asset pricing is important because the sensitivity of the asset returns to the observable risk factors varies over the securities.

This paper assumes that the group membership \( g_i \) (\( i = 1, 2, ..., N \)) is known. This assumption is motivated by empirical applications such as Goyal et al. (2008) as well as our own application in this paper. It might be of interest to let \( g_i \) be unknown and be estimated. This problem has been considered by Ando and Bai (2013) under the setting that the slope coefficients are homogeneous \((\beta_i = \beta \text{ for all } i)\) or there are \( G \) set of group-dependent coefficients. Such a model appears to be restrictive for asset pricing models for which the beta coefficients should be asset dependent. It is an interesting future research topic to allow both unknown group membership and asset-dependent coefficients.

In the appendix, we provide the regularity conditions of the model. Here, we briefly describe the assumptions. We assume the existence of \( r \) common pervasive
factors and $r_g$ group-specific pervasive factors $g = 1, ..., G$. Also, we allow weak serial and cross-sectional correlations on $\varepsilon_{it}$. Heteroscedasticity is also allowed even though $\varepsilon_{it}$ is assumed to have a finite eighth moment. This moment condition is a technical assumption that simplifies the theoretical analysis; it is not a necessary condition. For example, for the student-$t$ distribution with 5 degrees of freedom, the simulation shows that the procedure performs very well.

We point out that the observable risk factors can be correlated with the factor loadings, or with the unobserved common/group-specific pervasive factors, or can be correlated with both the factor loadings and the unobserved common/group-specific pervasive factors. Such correlations imply that panel regression without taking into account the factor structure will give rise to inconsistent estimation of the betas. A similar setting is considered by Bai (2009), in which the regression coefficients are common (not varying with $i$), and there are only a small number of explanatory variables, and there are no group-specific factors.

In the absence of observable risk factors and group-specific pervasive factors, model (1) reduces to a pure factor model, which has attracted much research interest in recent years. Factor models are perhaps the most commonly used statistical tool to simplify the analysis of huge panel data sets. Indeed, lately, many efforts in the econometric and statistical literature have been devoted to factor models for analyzing high-dimensional data. There are various types of factor specifications, including a dynamic exact factor model (Geweke, 1977; Sargent and Sims, 1977), a static approximate factor model (Chamberlain and Rothschild, 1983), a generalized dynamic factor model (Forni et al., 2000, Forni and Lippi, 2001; Amengual and Watson, 2007), and Bayesian factor models (Aguilar and West, 2000; Lopes and West, 2004; Tsay and Ando, 2012).

Remark: When a component of $x_{it}$ is set to 1, the model includes alphas ($\alpha_i$). Alternatively, let $\alpha_{it} = x_{it}'\beta_i$, the model allows a time-varying alpha that depends on the observable variables $x_{it}$. Ferson and Harvey (1999) examine time-varying alphas using
observable predictors. Some components of $\mathbf{x}_t$ can be common (not varying in $i$), such as market indices and Fama and French (1993)’s three factors (i.e., the excess return on the market, the growth factor, and the size factor). In general, $\mathbf{x}_t$ may consist of two sets of variables, with one set being the predictors of time-varying alphas, with the other being the state variables in the context of intertemporal CAPM (Merton, 1973). The interactions between the two sets of variables can also be included; this will also allow time-varying betas, as in Ferson and Harvey (1999). In empirical applications, $\mathbf{x}_t$ may also contain macroeconomic variables. Chen et al. (1986) studied the role of macroeconomic variables in asset pricing models. They found that some macroeconomic variables, including the spread between long and short interest rates, inflation and industrial production, systemically affect stock market returns. Ludvigson and Ng (2009) studies macro factors in bond returns. In our empirical applications, we also consider macroeconomic factors, and examine whether the observable risk factors as well as unobservable risk factors are priced in the cross section of returns.

Model (1) encompasses a number of often used asset pricing models. If there are no observable risk factors, the model reduces to a pure approximate factor model (Chamberlain and Rothschild, 1983; Connor and Korajczyk, 1986, 1988; Jones, 2001; Bai and Ng, 2002; Bai, 2003, Korajczyk and Sadka, 2008); or the grouped-factor model (Krzanowski, 1979; Flury, 1984; Bekaert et al., 2009; Wang, 2010).

As pointed out by Goyal et al. (2008), in an economy partitioned into several groups, the existence of common pervasive factors and group-specific pervasive factors is not ruled out by APT. The theory of APT permits both observable and unobservable factors. Therefore, model (1) can be justified from the APT’s perspective. Model (1) is also empirically appealing. Our estimation method will determine whether there exist common and group-specific factors.
3 Estimation and Asymptotic theory

3.1 Estimation

There exist several studies in the absence of observable risk-factor components. To estimate a model similar to the model (1) with $\beta_i = 0$ for $i = 1, ..., N$. Bekaert et al. (2009) proposed the two-step inference procedure. Flury (1984) considered the situation in which the $S$ groups have a common subspace for all groups. Schott (1999) considered the estimation procedure for a different setting. Goyal et al. (2008) proposed a multigroup factor model as an extension of Connor and Korajczyk (1986,1988). These studies either do not consider observable factors or only a small number of them or there are no unobservable factors. Pesaran (2006), Chuidk and Pesaran (2013), and Song (2013) allow a small number of observable regressors, without group-specific factors. The limitation of Pesaran’s estimation procedure is discussed by Westerlund and Urbain (20013).

We consider the situation for which there are a large number of possible observable risk factors, $p_i$, for security $i$, whereas the number of truly relevant observable risk factors is not large. In other words, the true underlying structure has a sparse representation and almost all elements of $\beta_i$ are zero, but which coefficients being zero are unknown. To identify the correct sparse representation of the regression coefficients $\beta_i$, we use the lasso-based approach (Tibshirani, 1996) for variable selection. Although the lasso method is widely used, shrinkage introduced by the lasso results in a bias towards zero for large regression coefficients. To diminish this bias, we use the smoothly clipped absolute deviation (SCAD) penalty approach (Fan and Li, 2001). As the SCAD method estimates redundant parameters for the irrelevant observable risk factors as zero (variable selection consistency), the computational cost is much less than the traditional variable selection methods. While the number of observable factors can be large, needless to say, our method works with a small number of observable
factors.

3.1.1 Estimation procedure

To estimate the unknown parameters given the number of common pervasive factors, \( r \), and the number of group-specific pervasive factors \( r_1, \ldots, r_S \), we minimize the least-squares objective function with a penalty term as follows:

\[
\ell(\beta_1, \ldots, \beta_N, F_c, F_1, \ldots, F_G, \Lambda_c, \Lambda_1, \ldots, \Lambda_G | r, r_1, \ldots, r_G, \kappa) = \sum_{i=1}^N \| y_i - X_i \beta_i - F_c \lambda_{c,i} - F_g \lambda_{g,i} \|^2 + T \sum_{i=1}^N p_{\kappa,\gamma}(\| \beta_i \|) \tag{2}
\]

subject to the constraints \( F_c' F_c / T = I_r \) and \( \Lambda_c' \Lambda_c \) being diagonal for the common pervasive factor and the corresponding \( r \times N \) factor-loading matrix \( \Lambda_c = (\lambda_{c,1}, \ldots, \lambda_{c,N}) \), and \( F_g' F_g / T = I_{r_g} \) \((g = 1, \ldots, G)\) and \( \Lambda_g' \Lambda_g \) \((g = 1, \ldots, G)\) being diagonal for the group-specific pervasive factor and the corresponding \( r_g \times N_g \) factor-loading matrices \( \Lambda_g = (\lambda_{g,1}, \ldots, \lambda_{g,N_g}) \). These restrictions are needed to avoid the model-identification problem and are commonly used in the literature (Connor and Korajczyk, 1986; Bai and Ng, 2002; Stock and Watson, 2002). For separating common pervasive and group-specific pervasive factors, we further assume \( F_c' F_g = 0 \) for \( g = 1, \ldots, G \). As shown by Wang (2010), this orthogonality condition is necessary even for models without regressors. But it can be shown that the estimated beta coefficients are invariant to whether this normalization restriction is made.

Here, \( \sum_{i=1}^N p_{\kappa,\gamma}(\| \beta_i \|) \) is a function of the coefficients indexed by a parameter \( \kappa \) that controls the tradeoff between the fitness and the penalty. To identify a smaller subset of important variables from each \( X_i \), we can search through subsets of potential observable risk factors for an adequate model. However, Breiman (1996) pointed out that this can be unstable and is computationally unfeasible. To avoid such problems, we use penalized regression procedures by shrinking some coefficients so that they are exactly equal to zero. This operation is equivalent to selection of the relevant observable risk factors. Some methods have been introduced for this purpose, including the lasso
method (Tibshirani, 1996), the SCAD penalty (Fan and Li, 2001), and the minimax concave penalty (Zhang, 2010). These methods were introduced for non-panel data models. Here we use the penalty method for panel data models and with the presence of factor errors.

The SCAD penalty is defined as

\[ p_{\kappa, \gamma}(|\beta_{ij}|) = \sum_{j=1}^{p} p_{\kappa, \gamma}(|\beta_{ij}|) \]

with:

\[ p_{\kappa, \gamma}(|\beta_{ij}|) = \begin{cases} \kappa |\beta_{ij}| & (|\beta_{ij}| \leq \kappa) \\ \gamma \kappa |\beta_{ij}| - 0.5(\beta_{ij}^2 + \kappa^2) & (\kappa < |\beta_{ij}| \leq \gamma \kappa) \\ \kappa^2 \left( \frac{\gamma - 1}{\gamma^2 - 1} \right) & (\gamma \kappa < |\beta_{ij}|) \end{cases} \]

for \( \kappa > 0 \) and \( \gamma > 2 \). This penalty first applies the same rate of penalization as the regular lasso and then reduces the rate to zero as the magnitude of beta coefficients moves further away from zero. Theoretical property of the the SCAD penalty is investigated in Fan and Li (2001) in the context of non-panel data.

If we take an extremely large value of the regularization parameter \( \kappa \), almost all estimated \( \beta_i \) will be estimated as zero even the true values are nonzero. In such a case, we might exclude important observable risk factors. Conversely, too small a regularization parameter might include a number of unrelated observable risk factors because almost all elements of \( \beta_i \) will not vanish at zero. Therefore, we need to balance these options and determine a proper size for the regularization parameter \( \kappa \).

We provide the model-selection criterion to select an optimal penalty size in the next section.

Joint minimization of the least-squares objective function with a penalty term can be done using the method by Bai (2009). Under the homogeneous slope coefficients (\( \beta = \beta_1 = \cdots = \beta_N \)) and the absence of the group-specific pervasive factors, Bai (2009) proposed to estimate the homogeneous slope coefficients jointly with the common pervasive factors and the corresponding factor loadings. His estimator of the homogeneous slope coefficients is \( \sqrt{NT} \) consistent even in the presence of serial or cross-sectional correlations and heteroscedasticities of unknown form in the error term.
Given \( \{\beta_1, \ldots, \beta_N\} \) and the group-specific pervasive factors \( F_{g,i} \lambda_{g,i} \), \( i = 1, \ldots, N \), we define the matrix \( W_c = (w_{c,1}, \ldots, w_{c,N}) \) of dimension \( T \times N \) with:

\[
w_{c,i} = y_i - X_i \beta_i - F_{g,i} \lambda_{g,i}.
\]

Then, the original model (1) reduces to \( w_{c,i} = F_c \lambda_{c,i} + \varepsilon_i \), which implies that \( W_c \) has a pure factor structure.

The least-squares objective function with the penalty is then:

\[
\text{tr} \left\{ (W_c - F_c \Lambda_c') (W_c - F_c \Lambda_c')' \right\} + T \sum_{i=1}^{N} p_{\kappa,\gamma} (|\beta_i|).
\]

From the analysis of pure factor models estimated by the method of least squares (i.e., principal components; see Connor and Korajczyk, 1986; Bai and Ng, 2002; Stock and Watson, 2002; Bai, 2009). By concentrating out \( \Lambda_c = W_c' F_c (F_c' F_c)^{-1} = W_c' F_c / T \), the objective function becomes:

\[
\text{tr} \{ W_c' W_c \} - \text{tr} \{ F_c' W_c W_c' F_c \} / T + T \sum_{i=1}^{N} p_{\kappa,\gamma} (|\beta_i|). \quad (3)
\]

Therefore, minimizing the objective function (3) with respect to \( F_c \) is equivalent to maximizing \( \text{tr} \{ F_c' W_c W_c' F_c \} \), subject to the constraint \( F_c' F_c / T = I_r \). Noting that the penalty term is not related to \( F_c \), the principal-component estimate of \( F_c \) subject to the constraint, \( \hat{F}_c \), is \( \sqrt{T} \) times the eigenvectors corresponding to the \( r \) largest eigenvalues of the \( T \times T \) matrix \( W_c W_c' \). Given \( \hat{F}_c \), the factor-loading matrix can be obtained as \( \hat{\Lambda}_c' = \hat{F}_c' W_c / T \). See also Bai and Ng (2002:197–198).

Next, given \( \{\beta_1, \ldots, \beta_N\} \), and the common pervasive factor structure \( F_c \Lambda_c \), we define the variable \( W_g = (w_{g,1}, \ldots, w_{g,N_g}) \) with \( w_{g,i} = y_i - X_i \beta_i - F_c \lambda_{c,i} \) as the set of \( N_g \) asset return series belonging to the \( g \)-th group. Note that only the \( N_g \) asset return series will be used for the estimation of the group-specific pervasive factor structures \( F_{g,i} \lambda_{g,i} \) of the \( g \)-th group. Then, based on a similar argument to that made above, the original model (1) reduces to the structure \( w_{g,i} = F_g \lambda_{g,i} + \varepsilon_{g,i} \). Again, this implies that the data matrix \( W_g \) (dimension of \( T \times N_g \)) has a pure factor structure and we can
estimate $F_g$ and $\lambda_{g,i}$ using the principal-component method. Estimates of the group-specific pervasive factor $F_g$ and the corresponding factor loading $\lambda_{g,i}$ can be obtained by minimizing the objective function:

$$\text{tr}\left\{ (W_g - F_g\Lambda_g') (W_g - F_g\Lambda_g')' \right\},$$

subject to the constraint $F_g'F_g/T = I_{r_g}$, for $g = 1, ..., G$. The principal-component estimate subject to the constraint can be obtained in a similar manner as described in the estimation of $F_c$ and $\Lambda_c$.

Although the estimates of $\{\beta_1, \ldots, \beta_N\}$, $\{F_c, \Lambda_c\}$, and $\{F_g, \lambda_g; g = 1, ..., G\}$ depend on each other, the estimators are obtained by using the following iterative algorithm.

**Estimation algorithm**

Step 1. Fix the regularization parameter, $\kappa$, the number of common pervasive factors, $r$, and the number of group-specific factors $\{r_1, ..., r_G\}$. Initialize the unknown regression coefficients $\{\beta_1^{(0)}, \ldots, \beta_N^{(0)}\}$, the pervasive common factors, and the corresponding factor-loading matrix $\{F_c^{(0)}, \Lambda_c^{(0)}\}$, as well as the group-specific pervasive factors and the corresponding factor-loading matrices $\{F_g^{(0)}, \lambda_g^{(0)}; g = 1, ..., G\}$.

Step 2. Given values of $\{\beta_1, \ldots, \beta_N\}$ and $\{F_g, \lambda_g; g = 1, ..., G\}$, update $\{F_c, \Lambda_c\}$.

Step 3. Given values of $\{\beta_1, \ldots, \beta_N\}$ and $\{F_c, \Lambda_c\}$, update $\{F_g, \lambda_g\}$ for $g = 1, ..., G$.

Step 4. Given values of $\{F_c, \Lambda_c\}$ and $\{F_g, \lambda_g; g = 1, ..., G\}$, update $\{\beta_1, \ldots, \beta_N\}$.

Step 5. Repeat Steps 2 and 4 until convergence.

In Step 1, starting values for $\{\beta_1, \ldots, \beta_N\}$, $\{F_c, \Lambda_c\}$, and $\{F_g, \lambda_g; g = 1, ..., S\}$ are needed. In the next section, we discuss how to prepare initial parameter values for these parameters.

### 3.1.2 Initial parameter values

We set the initial values as follows. First, by ignoring the common pervasive factor structure for all group $\{F_c, \Lambda_c\}$ and the group-specific pervasive factor structure for
each group \( \{F_g, \Lambda_g; \ g = 1, \ldots, G\} \), an initial estimate of \( \{\beta_1^{(0)}, \ldots, \beta_N^{(0)}\} \) is obtained using the pure SCAD approach. Second, given values of \( \{\beta_1^{(0)}, \ldots, \beta_N^{(0)}\} \), an initial estimate of the factor structures \( \{F_c, \Lambda_c\} \) is estimated by ignoring the group-specific pervasive factor structure for each group \( \{F_g, \Lambda_g; \ g = 1, \ldots, G\} \). Finally, given values of \( \{\beta_1^{(0)}, \ldots, \beta_N^{(0)}\} \) and the common pervasive factor structure for all of group \( \{F_c^{(0)}, \Lambda_c^{(0)}\} \), we obtain the starting values of the group-specific pervasive factor structure \( \{F_g^{(0)}, \Lambda_g^{(0)}\} \) for \( g = 1, \ldots, G \).

It is known that the least-squares objective function is not globally convex (see also Bai, 2009). In other words, an arbitrary starting value will not necessarily provide the global optimal solution. To maximize the chance of obtaining the global minimum, one may prepare several starting values. After the convergence, one may choose the estimators that give a smaller value of the objective function.

Here is an alternative parameter initialization. First, by ignoring the effect from the observable risk factors, \( \{X_i \beta_i; \ i = 1, \ldots, N\} \), and the group-specific factor structures \( \{F_g, \Lambda_g; \ g = 1, \ldots, G\} \), we obtain an initial estimate of the common pervasive factor structure \( \{F_c^{(0)}, \Lambda_c^{(0)}\} \). Then, given \( \{F_c^{(0)}, \Lambda_c^{(0)}\} \), by ignoring the effect from the observable risk factors, \( \{X_i \beta_i; \ i = 1, \ldots, N\} \), we obtain a starting value of the group-specific factor structures \( \{F_g, \Lambda_g\} \) for \( g = 1, \ldots, G \). Finally, we obtain an initial value of \( \{\beta_1^{(0)}, \ldots, \beta_N^{(0)}\} \).

Under large \( N \) and large \( T \), however, the convergence is quite robust to initial values. Also, the convergence is faster, that is, the number of iterations to achieve convergence is much smaller than under small \( N \) or small \( T \). As a practical guide, for both \( N \) and \( T \) greater than 50, choice of initial values is less of a concern.

Simulation results in Section 5 indicate that the estimation method above is robust to the starting values. The results reveal that among the 1000 Monte Carlo repetitions, the converged parameter values \( \hat{\beta}_i \) with the above two starting values reached the same point more than 95% of times. If the converged values are different, we then select the
one that minimizes the objective function.

### 3.2 Discussion on the estimation

In this section, we provide some remarks on the proposed estimation procedure. First, in principle, when one knows a priori that two or more markets are different, one could also conduct separate analyses for each market. This would be a good strategy if there exist no common pervasive factors. Separate analysis for each group makes it difficult to tell if these groups share common-pervasive factors, especially unobservable ones. In addition, pooling groups together allows more efficient estimation of unobservable common factors. Therefore, it is desirable to model simultaneously the common pervasive structures, the group-specific pervasive structures, the observable risk factor components by pooling groups.

Second, instead of the variable selection approach in selecting the observable factors for each asset $i$, one might use the methodology of Stock and Watson (2005) to extract some principal components from the explanatory variables $X_i$ or other macroeconomic and financial variables. These principal components could be used as regressors in the model and one could evaluate which principal components are important for which asset groups. This principal component method is an alternative way to reduce the dimensionality problem since the dimension of $X_i$ ($p_i \times T$) can be large ($p_i$ is large). This two-step procedure is very useful for forecasting, it is less desirable than the procedure introduced in this paper. The regressors $X_i$ depend on $i$, they are not common to all individual assets. That is, many observable risk factors in $X_i$ are security-specific, e.g., profitability, firm size, etc. An alternative is to do a principal components analysis for each firm using data matrix $X_i$ ($p_i \times T$). There is no obvious advantage for doing this. The current procedure directly selects the relevant regressors, and the resulting selected variables have direct economic interpretation.

Third, it is straightforward to put an additional penalty term in (2) that penalizes
the factor loadings on the common or group-specific pervasive factors. However, by the
definition, the group-specific pervasive factors affect almost all security returns within
each group and the common factors affect almost all securities in all groups by the
pervasive nature, penalizing these coefficients may not be desirable. Moreover, it is
unlike to overfit the model due to the factor loading estimation because the dimension
of the group-specific pervasive factors is usually small. Therefore, the penalty term
on the factor loadings is not used. In contrast, the number of possible observable risk
factors may be potentially very large at the initial modeling stage. For these reasons,
we use the shrinkage method only on the parameters of observable factors. Also, the

group factor structure has implicitly put many zero restrictions on the loadings (zero
loadings for assets outside its own group). Furthermore, the number of factors is
determined by the information criterion approach (a different penalty method to be
considered below).

Fourth, the proposed model can also be estimated by the Bayesian procedure. In-
stead of using penalization, shrinkage priors on $\beta_i$ can be used, e.g., Hans (2009),
Park and Casella (2008), and Polson and Scott (2012). Also, the priors on the
common/group-specific pervasive factors and corresponding factor loadings are con-
sidered in the literature, e.g., Tsay and Ando (2012). Because the joint posterior
density does not have an analytical expression, one needs to implement the Markov
chain Monte Carlo (MCMC) approach. The details are beyond the scope of this paper.

Fifth, the SCAD penalty shrinks some elements of $\beta_i$ ($i = 1, ..., N$) to exactly zero.
This operation is equivalent to selecting relevant observable risk factors. So the set
of observable risk factors are automatically determined once the size of regularization
parameter kappa ($\kappa$) is fixed. That is, the selection of the set of relevant observable
risk factors is equivalent to the determination of the size of regularization parameter
$\kappa$. The determination of $\kappa$ is through a $C_p$ criterion introduced in Section 5.

Finally, as in Assumption D (See Appendix), we exclude the situation in which
the observable risk factors and underlying unobservable common factors are correlated perfectly. If they are perfectly correlated, then the dimension of unobservable common factors is automatically reduced since they are already included in the regressors. The dimension of the common factors is determined by the information criterion, which will not select a common factor that is already a part of observable factors. The information criterion method produces a parsimonious model. Thus the assumption of non-perfect correlation is without loss of generality.

3.3 Asymptotic theory for inference

The previous sections described the model, its assumptions, and the estimation procedure. This section investigates the asymptotic properties of the parameter estimates. We denote the true value of regression coefficients as $\beta_i^0$, the true value of common pervasive factors that affect the returns of all securities as $F_c^0$, and the true value of group-specific pervasive factors by $F_g^0$. Also we let $\|A\| = [\text{tr}(A'A)]^{1/2}$ be the usual norm of the matrix $A$, where “tr” denotes the trace of a square matrix. The equation $a_n = O(b_n)$ states that the deterministic sequence $a_n$ is at most of order $b_n$, $c_n = O_p(d_n)$ states that the random variable $c_n$ is at most of order $d_n$ in probability, while $c_n = o_p(d_n)$ means that $c_n$ is of a smaller order than $d_n$ in probability. All asymptotic results are obtained under large $N$ and large $T$.

We first consider the consistency of the estimators of the regression coefficients $\beta_i$, $i = 1, \ldots, N$, the common pervasive factors $F_c$, and the group-specific pervasive factors $F_g$, $g = 1, \ldots, G$. As the number of elements in $F_c$ and $\{F_g, \ g = 1, \ldots, G\}$ is increasing in $T$, we prove consistency in terms of a matrix norm. Also, we emphasize that the size of the regularization parameter depends on the length of the time series $T$, and thus is denoted by $\kappa_T$. Then, we have the following theorem.

**Theorem 1** Under Assumptions A-E given in the appendix, and $\kappa_T \to 0$ and $\sqrt{T} \kappa_T \to$
as \( T \to \infty \), the estimator \( \hat{\beta}_i \) is consistent such that
\[
\| \hat{\beta}_i - \beta_i \| = o_p(1)
\]
In addition, the estimators of the common pervasive factors \( \hat{F}_c \) and the group-specific pervasive factors \( \{ \hat{F}_g, \ g = 1, \ldots, G \} \) are consistent in the sense of the following norm:
\[
T^{-1/2} \| \hat{F}_c - F^0_c H_c \| = o_p(1), \quad T^{-1/2} \| \hat{F}_g - F^0_g H_g \| = o_p(1),
\]
where:
\[
H^{-1}_c = V_{c,NT}(F^0_c \hat{F}_c / T)(N_c \Lambda_c / N)^{-1}, \quad H^{-1}_g = V_{g,NgT}(F^0_g \hat{F}_g / T)(N_g \Lambda_g / N_g)^{-1},
\]
and \( V_{c,NT} \) and \( V_{g,NgT} \) satisfies:
\[
\frac{1}{NT} \sum_{g=1}^G \sum_{i: g_i = g} (y_i - \hat{X}_i \hat{\beta}_i - \hat{F}_g \hat{\lambda}_{g,i})(y_i - \hat{X}_i \hat{\beta}_i - \hat{F}_g \hat{\lambda}_{g,i})' \hat{F}_c = \hat{F}_c V_{c,NT}
\]
and
\[
\frac{1}{NgT} \sum_{i: g_i = g} (y_i - \hat{X}_i \hat{\beta}_i - \hat{F}_c \hat{\lambda}_{c,i})(y_i - \hat{X}_i \hat{\beta}_i - \hat{F}_c \hat{\lambda}_{c,i})' \hat{F}_g = \hat{F}_g V_{g,NgT}.
\]
In the preceding theorem, \( H_c \) and \( H_g \) are rotational matrices, their exact expressions are not crucial. The last two equations of Theorem 1 show that \( \hat{F}_c \) and \( \hat{F}_g \) are the eigenvectors of the corresponding matrices inside the square brackets.

The proof of Theorem 1 is presented in the Appendix. Given the consistency, we further establish the asymptotic normality of the estimated parameters. Also, we show that our proposed method can identify the set of true explanatory variables. Let \( \beta_i^0 = (\beta_{i10}', \beta_{i20}')' \) be the true parameter value, and \( \hat{\beta}_i = (\hat{\beta}_{i1}', \hat{\beta}_{i2}')' \) be the corresponding parameter estimate. Without loss of generality, we assume that \( \beta_{i20} = 0 \). We also assume that the dimension of \( \beta_{i10} \) is small (uniformly bounded over \( i \)) but the dimension of \( \beta_{i20} \) can be large. We show that the estimator possesses the sparsity property, \( \hat{\beta}_{i2} = 0 \). We denote \( \hat{\beta}_{i1} \) as the parameter estimate of non-zero true coefficients \( \beta_{i10} \). We impose the following assumption, which is necessary for the asymptotic normality of \( \beta_i \). The limiting results are useful for hypothesis testing.
Define the projection matrices

\[
M_{Fc} = I - F_c(F'_c F_c)^{-1} F'_c \\
M_{Fc, Fg} = M_{Fc} - M_{Fc} F_g (F'_g M_{Fc} F_g)^{-1} F'_g M_{Fc}
\]

The second projection matrix is also equal to \( M_G = I - G(G')^{-1} G \) with \( G = [F_c, F_g] \).

Let \( X_{i, \beta_0^i \neq 0} \) be the columns of \( X_i \) corresponding to nonzero coefficients of \( \beta_0^i \); let \( q_i \) denote the number of columns of \( X_{i, \beta_0^i \neq 0} \), and \( \beta_{i, 10} = (\beta_{i, 11}^0, \beta_{i, 12}^0, \ldots, \beta_{i, q_i}^0)' \) be the vector of non-zero coefficients of \( \beta_0^i \).

**Theorem 2** Suppose that the \( i \)-th security belongs to group \( g \) and that Assumptions A-H hold. Furthermore, the regularization parameter satisfies \( \kappa_T \to 0 \) and \( \sqrt{T \kappa_T} \to \infty \) as \( T \to \infty \). Then, as \( T, N \to \infty \) with \( \sqrt{T}/N \to 0 \), the following variable-selection consistency holds:

\[
P(\hat{\beta}_{i, 2} = 0) \to 1, \quad N, T \to \infty.
\]

Moreover, \( \sqrt{T}(\hat{\beta}_{i, 1} - \beta_{i, 10}) \) is asymptotically normal with mean \( 0 \) and variance-covariance matrix \( R_i(F_c^0, F_g^0) \),

\[
\sqrt{T}(\hat{\beta}_{i, 1} - \beta_{i, 10}) \to_d N(0, R_i(F_c^0, F_g^0)),
\]

where

\[
R_i(F_c^0, F_g^0) = D_i(F_c^0, F_g^0)^{-1} J_i(F_c^0, F_g^0) D_i(F_c^0, F_g^0)^{-1},
\]

and \( D_i(F_c^0, F_g^0) \) and \( J_i(F_c^0, F_g^0) \) are the probability limits (in terms of \( T \to \infty \)) of:

\[
\frac{1}{T} \left( X'_{i, \beta_0^i \neq 0} M_{F_c^0, F_g^0} X_{i, \beta_0^i \neq 0} + \Sigma_i(\kappa_T) \right), \quad \text{and} \\
\frac{1}{T} \left( X'_{i, \beta_0^i \neq 0} M_{F_c^0, F_g^0} E[\epsilon_i\epsilon'_i] M_{F_c^0, F_g^0} X_{i, \beta_0^i \neq 0} \right),
\]

respectively, with

\[
\Sigma_i(\kappa_T) = \text{diag}\left\{ p'_{\kappa_T, \gamma}(|\beta_{i, 11}^0|)/|\beta_{i, 11}^0|, \ldots, p'_{\kappa_T, \gamma}(|\beta_{i, q_i}^0|)/|\beta_{i, q_i}^0| \right\}.
\]
A proof of Theorem 2 is given in the supplementary document. Note that $\sqrt{T}/N \to 0$ is not a strong assumption; the number of securities $N$ can be much larger than the number of time periods $T$, and the number of time periods $T$ can also be much larger than $N$. Although restrictions between $N$ and $T$ are needed in terms of simultaneous limit ($N, T \to \infty$), the theorem holds not only for a particular relationship between $N$ and $T$, but also for many combinations of $N$ and $T$. The theorem allows us to perform statistical significance test for coefficients $\beta_i$. We discuss the estimators of $D_i(F_c^0, F_g^0)$ and $J_i(F_c^0, F_g^0)$ in Section 5.

4 Implementation and Simulation Analysis

4.1 Model specification

In practice, however, the number of common pervasive factors, $r$, and the number of group-specific pervasive factors, $\{r_1, ..., r_G\}$, are unknown. Moreover, we have to select the size of the regularization parameter $\kappa$ such that the relevant observable risk factors are included, while excluding irrelevant observable risk factors. In this section, we propose a new criterion to select these quantities.

4.1.1 A model-selection criterion

Suppose that $z_1, \ldots, z_N$ are replicates of the asset returns $y_1, \ldots, y_N$, given the true value of common pervasive factors $F_c$ and the corresponding factor loadings $\Lambda_c$, and given the group-specific pervasive factors $F_g$ and the corresponding factor loadings $\Lambda_g$, $g = 1, ..., G$, and the observable factors $X_i$ ($i = 1, \ldots, N$). In other words, we assume that the $z_i$’s are generated from the true underlying structure of the economy. This situation is commonly considered in model-selection studies; see, for example, Konishi and Kitagawa (1996), Hansen (2005), Ando and Tsay (2010), and references therein.

To assess the goodness of fit of the estimated model, we use the expected mean
squared errors (MSE):

\[ \eta(k, k_1, \ldots, k_G, \kappa) := E_z \left[ \frac{1}{NT} \sum_{g=1}^{G} \sum_{i: g_i = g} \| z_i - X_i \hat{\beta}_i - \hat{F}_c \hat{\lambda}_{c,i} - \hat{F}_g \hat{\lambda}_{g,i} \|_2^2 \right], \]

(4)

where \( k \) is the number of common pervasive factors, \( k_1, \ldots, k_G \) are the number of group-specific pervasive factors for each group, \( \kappa \) is the regularization parameter, and the expectation is taken with respect to the joint distribution of \( z_1, \ldots, z_N \). The quantities \( k, k_1, \ldots, k_G, \kappa \) are chosen by minimizing the expected MSE.

A natural estimator of the expected MSE in (4) is the sample-based MSE:

\[ \hat{\eta}(k, k_1, \ldots, k_G, \kappa) := \frac{1}{NT} \sum_{g=1}^{G} \sum_{i: g_i = g} \| y_i - X_i \hat{\beta}_i - \hat{F}_c \hat{\lambda}_{c,i} - \hat{F}_g \hat{\lambda}_{g,i} \|_2^2. \]

(5)

This quantity is formally calculated by replacing the replicates \( z_i \) with observed values \( y_i \), and \( \hat{F}_c \) and \( \hat{F}_g \) are estimated with \( k \) and \( k_g \) number of factors, respectively; \( \hat{\beta}_i \) is estimated with the SCAD penalty with kappa (\( \kappa \)) as the tuning parameter. This sample-based MSE generally has some bias with respect to the expected MSE because, among other reasons, the same data are used to estimate the parameters of the model. We therefore consider a bias-corrected version of the measure.

The bias \( b \) of the sample-based MSE with respect to the expected MSE is given by:

\[ b(k, k_1, \ldots, k_G, \kappa) := E_y [\eta(k, k_1, \ldots, k_G, \kappa) - \hat{\eta}(k, k_1, \ldots, k_G, \kappa)], \]

(6)

where the expectation is taken with respect to the joint distribution of \( y_i (i = 1, \ldots, N) \).

We assume that the bias \( b(k, k_1, \ldots, k_G, \kappa) \) can be estimated by some appropriate procedures, yielding \( \hat{b}(k, k_1, \ldots, k_G, \kappa) \). Taking into account the consistency of the proposed model-selection criterion, we suggest minimization of the predictive measure:

\[ \hat{\eta}(k, k_1, \ldots, k_G, \kappa) + \hat{b}(k, k_1, \ldots, k_G, \kappa) \]

\[ = \frac{1}{NT} \sum_{g=1}^{G} \sum_{i: g_i = g} \| y_i - X_i \hat{\beta}_i - \hat{F}_c \hat{\lambda}_{c,i} - \hat{F}_g \hat{\lambda}_{g,i} \|_2^2 + \hat{b}(k, k_1, \ldots, k_G, \kappa). \]

(7)

The first term on the right-hand side, \( \hat{\eta}(k, k_1, \ldots, k_G, \kappa) \), measures the goodness of fit of the model, whereas the second term, \( \hat{b}(k, k_1, \ldots, k_G, \kappa) \), is a penalty that depends on
the complexity of the model. The remaining task is to construct a proper estimator of the penalty term. Another contribution of this paper is the following theorem.

**Theorem 3** Suppose that Assumptions A–E and the condition \( \sqrt{T}/N \to 0 \) hold. The penalty term is then:

\[
\hat{b}(k, k_1, ..., k_G, \kappa) = \frac{1}{NT} \sum_{g=1}^{G} \sum_{i: g_i = g} \text{tr} \left[ K_i R_i(F^0_c, F^0_{g_i}) \right]
+ k \times h(T, N, N_1, ..., N_G) + \sum_{g=1}^{G} k_g \times h_g(T, N, N_1, ..., N_G),
\]

where \( K_i = 2X_i'X_i/\delta_i \) is the submatrix of \( X_i \) such that the corresponding columns have a nonvanishing component of the parameter estimate, and \( R_i(F^0_c, F^0_{g_i}) \) is defined in Theorem 2. The functions \( h(T, N, N_1, ..., N_G) \) and \( h_g(T, N, N_1, ..., N_G) \) satisfy (a) \( h(T, N, N_1, ..., N_G) \to 0 \) and (b) \( \sqrt{T} h(T, N, N_1, ..., N_G) \to \infty \) as \( T, N \to \infty \), and similarly for \( h_g \).

A derivation of the theorem is given in the Appendix.

The first term on the right hand side of \( \hat{b}(k, k_1, ..., k_G, \kappa) \) in Theorem 3 controls the size of the regularization parameter. In other words, it is the term for including the relevant observable risk factors only among a large number of observable risk factors. The second term is relevant to the identification of the true number of common pervasive factors. Also, the quantity \( k_g \times h_g(T, N, N_1, ..., N_G) \) in the third term is used for selecting the number of group-specific pervasive factors \( r_g \) in the group \( g \).

An example of the function \( h(T, N, N_1, ..., N_G) \) that satisfies conditions (a) and (b) of the theorem is:

\[
h(T, N, N_1, ..., N_G) = \left( \frac{T + N}{TN} \right) \log(TN).
\]

Also, the similar function \( \left( \frac{T + N_g}{TN_g} \right) \log(TN_g) \) is used for \( h_g(T, N, N_1, ..., N_G) \). Substituting these quantities into the predictive measure (7), we have the following model-
selection criterion:

\[ C_p(k, k_1, \ldots, k_G, \kappa) = \frac{1}{NT} \sum_{g=1}^{G} \sum_{i:g_i=g} \| y_i - X_i \hat{\beta}_i - \hat{F}_c \hat{\lambda}_{c,i} - \hat{F}_{g_i} \hat{\lambda}_{g_i,i} \|^2 \]

\[ + \frac{1}{NT} \sum_{i=1}^{N} \text{tr} \left[ K_i R(\hat{F}_c, \hat{F}_{g_i}, \kappa) \right] \]

\[ + k \times \hat{\sigma}^2 \left( \frac{T + N}{TN} \right) \log (TN) + \sum_{g=1}^{G} k_g \times \hat{\sigma}^2 \left( \frac{T + N_g}{TN_g} \right) \log (TN_g), \tag{8} \]

where \( R(\hat{F}_c, \hat{F}_{g_i}, \kappa) \) is a consistent estimate of \( R_i(F^0_c, F^0_{g_i}) \), to be discussed in section 4.1.2, and \( \hat{\sigma}^2 \) is an estimate of \( \frac{1}{NT} \sum_{i=1}^{N} \sum_{t=1}^{T} E(\varepsilon^2_{it}) \).

We can choose the number of common pervasive factors, \( k \), the number of group-specific pervasive factors, \( k_g \) (\( g = 1, \ldots, G \)), and the size of the regularization parameter \( \kappa \), by minimizing the \( C_p \) over a specified range of models.

We can regard the proposed model-selection criterion as a generalization of the \( C_p \) criterion of Mallows (1973). Like the original \( C_p \) criterion, \( \hat{\sigma}^2 \) provides proper scaling for the penalty term. In applications, it can be replaced by \( (NT)^{-1} \sum_{g=1}^{G} \sum_{i:g_i=g} \| y_i - X_i \hat{\beta}_i - \hat{F}_c \hat{\lambda}_{c,i} - \hat{F}_{g_i} \hat{\lambda}_{g_i,i} \|^2 \), which is obtained under the maximum possible dimension of \( X_i \), the maximum possible number of common pervasive factors \( r_{c,max} \), and the maximum possible number of group-specific pervasive factors \( r_{g,max} \) (\( g = 1, \ldots, G \)).

Suppose that the number of common and group-specific factors is known, then the \( C_p \) criterion consists of the first two terms on the right hand of (8); and the criterion can be denoted by \( C_p(\kappa) \). For each \( \kappa \), we estimate the model by minimizing the objective function in (2) using the SCAD method. The first term on the right hand side of (8) is a by-product of the SCAD estimation. After obtaining \( \hat{\beta}_i \) from (2), we can easily compute \( K_i = 2X_i' \hat{\beta}_i \hat{\beta}_i' X_i / T \), as well as \( R(\hat{F}_c, \hat{F}_{g_i}, \kappa) \). This gives the second term on the right hand side of (8). Summing the two terms yields \( C_p(\kappa) \). We choose \( \kappa \) by minimizing \( C_p(\kappa) \) with respect to \( \kappa \). In practice, the minimization is done over a discrete set of candidate values of \( \kappa \).

The model-specification algorithm for determining the number of common pervasive
factors $r$, the number of group-specific pervasive factors $r_g$, and the size of regularization parameter $\kappa$, is summarized as follows.

**Model-specification algorithm**

Step 1. Prepare a set of candidate values of the regularization parameter $\kappa$, the number of common pervasive factors $k$, and the number of group-specific pervasive factors $\{k_1, \ldots, k_G\}$. Then, fix their initial values.

Step 2. Fix the value of regularization parameter $\kappa$ as one of the candidate values.

Step 3. Given the value of the regularization parameter $\kappa$ and the number of group-specific pervasive factors $\{k_1, \ldots, k_G\}$, optimize the number of common pervasive factors $k$ by minimizing the proposed $C_p$ criterion.

Step 4. Given the value of the regularization parameter $\kappa$ and the number of common pervasive factors $k$, optimize the number of group-specific pervasive factors $\{k_1, \ldots, k_G\}$ by minimizing the proposed $C_p$ criterion.

Step 5. Repeat Steps 3 and 4 until convergence.

Step 6. Repeat Steps 2–5 for each of the prepared regularization parameters $\kappa$. Then, select the combination of the regularization parameter $\kappa$, the number of global factors $k$, and the number of local factors $\{k_1, \ldots, k_G\}$, which minimize the proposed $C_p$ criterion.

Note that every evaluation of the $C_p$ criterion in (8) requires the minimization of (2). Thanks to an advantage of the SCAD procedure, the proposed criterion $C_p$ is applicable even when $p_i > T$, where $p_i$ is the number of possible observable risk factors.

**4.1.2 Some remarks on $C_p$ criterion**

In this section, we provide some remarks on the proposed $C_p$ criterion. First, the matrix $R(F_0^c, F_0^g)$ in the $C_p$ criterion is defined in Theorem 2, which involves matrices $D_i(F_0^c, F_0^g)$ and $J_i(F_0^c, F_0^g)$. These matrices can be estimated by their empirical versions. In the absence of serial and cross-section correlations in the idiosyncratic errors $(E[\varepsilon_{it}\varepsilon_{is}] = 0 \ (t \neq s), \ E[\varepsilon_{it}\varepsilon_{jt}] = 0 \ (i \neq j))$, the calculation of $J_i(F_0^c, F_0^g)$ can be
simplified as follows:

\[ J_i(\hat{F}_c, \hat{F}_g) = \frac{1}{T} X'_{i, \beta_i \neq 0} M_{\hat{F}_c, \hat{F}_g} \hat{\Omega}_i M_{\hat{F}_c, \hat{F}_g} X_{i, \beta_i \neq 0}, \]

where \( \hat{\Omega}_i = \text{diag}\{\hat{\varepsilon}^2_{i1}, ..., \hat{\varepsilon}^2_{iT}\} \) is a diagonal matrix, and \( \hat{\varepsilon}_{it} = y_{it} - \hat{\beta}_i x_{it} - \hat{f}'_{c,t} \hat{\lambda}_{c,i} - \hat{f}'_{g,t} \hat{\lambda}_{g,i} \). If we further assume the absence of heteroskedasticity (\( E[\varepsilon^2_{it}] = \sigma^2 \)), we can estimate \( J_i(F^0_c, F^0_g) \) by:

\[ J_i(\hat{F}_c, \hat{F}_g) = \frac{1}{T} \hat{\sigma}^2_i X'_{i, \beta_i \neq 0} M_{\hat{F}_c, \hat{F}_g} X_{i, \beta_i \neq 0}, \]

where \( \hat{\sigma}^2_i = T^{-1} \sum_{t=1}^T \hat{\varepsilon}^2_{it} \) is the variance estimator. The matrix \( D_i(F^0_c, F^0_g) \) is estimated by

\[ D_i(\hat{F}_c, \hat{F}_g) = \frac{1}{T} [X'_{i, \beta_i \neq 0} M_{\hat{F}_c, \hat{F}_g} X_{i, \beta_i \neq 0} + \hat{\Sigma}_i(\kappa)] \]

where \( \Sigma_i \) is defined in Theorem 2.

Second, the estimated number of common and group-specific pervasive factors allows us to measure the financial integration of markets. Consider a case in which the estimated number of group-specific pervasive factors in each group is zero, while the common pervasive factors exist. In this case, it is natural to regard the corresponding sub-markets are integrated. As a second case, the result may reveal that the number of common pervasive factors is identified as zero, while there exit group-specific pervasive factors in each group. In contrast to the first case, one would naturally think that the market decoupling is observed. In our empirical analysis, both common and group-specific pervasive factors exist. It implies that the Chinese A and B share markets are integrated, while each market has its own characteristics.

4.2 Simulation results

4.2.1 Data-generating processes

We consider a number of different data generating processes. The first one is \( y_i = X_i \beta_i + F_{c,i} \lambda_{c,i} + F_{g,i} \lambda_{g,i} + \varepsilon_i \), the \( r \)-dimensional common pervasive factor \( f_{c,t} \) is a vector of \( N(0,1) \) variables, the \( r_g \)-dimensional group-specific pervasive factor \( f_{g,t} \) j = 1, ..., S
is also a vector of $N(0, 1)$ variables, and each element of the factor-loading matrix $\Lambda$, 
$\{\Lambda_1, \ldots, \Lambda_G\}$ follows $N(0, 1)$. The $N$-dimensional vector $\varepsilon_t$ has a multivariate normal 
distribution with a mean of $0$ and covariance matrix $I_N$. The number of columns of $X_i$ is 
set to $p_i = 80$, while the true number of regressors is $q_i = 3$ for $i = 1, \ldots, N$. Each of the 
elements of $X_i$ is generated from the uniform distribution over $[-2, 2]$. The nonzero true 
parameter values of $\beta_i$ are set to be $(-1, 2, 2)$. These nonzero elements are put into the 
first three elements of $\beta_i$ and thus the true parameter vector is $\beta_i = (-1, 2, 2, 0, 0, ..., 0)'$ 
for $i = 1, \ldots, N$. The true number of common pervasive factors is $r = 5$, and the true 
numbers of group-specific pervasive factors are $r_1 = 2, r_2 = 3, r_3 = 4, r_4 = 4, r_5 = 5$. We next investigate a case in which the noise term is nonhomoscedastic.

The second data-generating model considered is $y_i = X_i\beta_i + F_c\lambda_{c,i} + F_g\lambda_{g,i} + \varepsilon_i$ and $\varepsilon_{it} = \varepsilon_{1t} + \delta_t \varepsilon_{2t}$, where $\delta_t = 1$ if $t$ is odd and is zero if $t$ is even, and the $N$-dimensional 
vectors $\varepsilon_1^t = (e_{11}^t, \ldots, e_{N1}^t)'$ and $\varepsilon_2^t = (e_{12}^t, \ldots, e_{N2}^t)'$ follow multivariate normal distributions, with a mean of $0$ and covariance matrix $S = (s_{ij})$, where $s_{ij} = 0.3^{i-j}$, and $\varepsilon_1^t$ and $\varepsilon_2^t$ are independent. The noise terms are not serially correlated. The common 
pervasive factors, the group-specific pervasive factors, the loading matrices, the design 
matrix $X_i$, and the true parameter vector $\beta_i$ are generated by the same method as 
before. The key feature of the model is that the noise terms are not homoscedastic.

As a third example, we investigated the performance of the proposed method when the 
idiosyncratic errors had some serial and cross-sectional correlations. The model is $y_i = X_i\beta_i + F_c\lambda_{c,i} + F_g\lambda_{g,i} + \varepsilon_i$ with $\varepsilon_{it} = \varepsilon_{it} + 0.2\varepsilon_{i,t-1}$, where $t = 1, \ldots, T$, 
the $N$-dimensional vector $\varepsilon_t = (e_{1t}, \ldots, e_{Nt})'$ follows multivariate normal distributions 
with mean $0$ and covariance matrix $S = (s_{ij})$, where $s_{ij} = 0.3^{i-j}$. Other variables are 
defined as before.

As a fourth example, we generated the data under a situation where the set of 
true observable risk factors $X_i$ are correlated with a set of $r$ common pervasive factors. 
Again, the model is $y_i = X_i\beta_i + F_c\lambda_{c,i} + F_g\lambda_{g,i} + \varepsilon_i$ with $\varepsilon_{it} = \varepsilon_{it} + 0.2\varepsilon_{i,t-1}$, where $t =$ 27
1, ..., T, the noise values \( e_t = (e_{1t}, \ldots, e_{Nt})' \) follow multivariate normal distributions with mean 0 and covariance matrix \( S = (s_{ij}) \), where \( s_{ij} = 0.3^{|i-j|} \). Also, we generated a set of \( r+2 \) dimensional random variables \( z_t = (z_{1t}, \ldots, z_{r+2,t})' \), which follow multivariate normal distributions with mean 0 and covariance matrix \( S = (s_{ij}) \), with \( s_{ij} = 0.3^{|i-j|} \).

Then, the first \( r \) elements of \( z_t, (z_{1t}, \ldots, z_{r,t})' \) are used for the common pervasive factors \( f_{c,t} \) and the remaining part of \( z_t = (z_{r+1,t}, z_{r+2,t})' \) is added to the first two elements of observable risk factors \( x_{it}, i = 1, \ldots, N \). This operation creates a situation in which the common pervasive factors and the observable risk factors have correlation structures. Other variables are defined as before.

As a fifth example, we generated the data under a situation where the set of true observable risk factors \( X_i \) are correlated with group-specific pervasive factors. We generated a set of \( r_1 + 2 \) dimensional random variables \( z_t = (z_{1t}, \ldots, z_{r_1+2,t})' \), which follow multivariate normal distributions with mean 0 and covariance matrix \( S = (s_{ij}) \), with \( s_{ij} = 0.3^{|i-j|} \). Then, the first \( r_1 \) elements of \( z_t, (z_{1t}, \ldots, z_{r_1,t})' \) are used for the group-specific pervasive factors \( f_{1,t} \) of group \( S_1 \), and then the remaining part of \( z_t, (z_{r+1,t}, z_{r+2,t})' \) was added to the first elements of observable risk factors \( x_{it}, i = 1, \ldots, N \). This operation creates a situation where the group-specific pervasive factors and the true observable risk factors have correlation structures. Other variables are defined as before.

In these simulation settings, we consider two cases: (1) the number of securities in each group is equal, i.e., \( N_1 = N_2 = \cdots = N_5 \), and (2) the number of securities in each group are different.

4.2.2 Results

We generated 1,000 replicates using each of the five data-generating processes. We then applied the proposed model-selection criterion, \( C_p \), to select simultaneously the number of common pervasive factors, the number of group-specific pervasive factors, and the
size of regularization parameter $\kappa$. We set the possible numbers of both common and group-specific pervasive factors to range from 0 to 10. Thus, the maximum number of common and group-specific pervasive factors were set to 10, respectively. Possible candidates for the regularization parameter $\kappa$ are $\kappa = \{10, 1, 0.1, 0.01, 0.001\}$. To speed up the computation of the $C_p$ criterion in (8), we used an estimator of $J_i(\hat{F}_c, \hat{F}_{g_i})$ in (9), which assumes the absence of serial correlations. However, as our results show that the criterion performs well, even if this assumption, i.e., the absence of serial correlation, does not hold. The model-selection results for the third example indicate that the $C_p$ criterion is robust to the misspecification of the noise characteristics.

Tables 1 reports the percentages for correct, under-, and overidentification of the proposed $C_p$ criterion under the five data-generating models. If the proposed method identifies the true number of common pervasive factors ($r$) 1,000 times out of 1,000 trials, the corresponding three columns with respect to $r$ become 0, 100, and 0 under U, C, and O, respectively. As shown in the tables, the proposed $C_p$ criterion is capable of selecting the true number of common and group-specific pervasive factors.

We next discuss the results on the estimated regression coefficients. For simplicity, we shall report the results obtained under the fourth data-generating process only, because other data settings have similar results. Simulation results for the parameter estimates of $\hat{\beta}_i$ are reported in Table 1. Because the theoretical properties of the parameter estimates $\hat{\beta}_i$ are common for each $i$, we report the results for $\hat{\beta}_1$ only. Again, given $T$ and $N$, similar results are obtained for $\hat{\beta}_2, \ldots, \hat{\beta}_N$. As shown in Table 2, the parameters are well estimated in the simulation studies. Because the length of $\hat{\beta}_1$ is very long (a vector of length 80), we report the estimation results for the true regressors $(\hat{\beta}_{1,1}, \hat{\beta}_{1,2}, \hat{\beta}_{1,3})'$, and those for the first three irrelevant regressors, $(\hat{\beta}_{1,4}, \hat{\beta}_{1,5}, \hat{\beta}_{1,6})$; the remaining elements of $\hat{\beta}_1$ (i.e., $\hat{\beta}_{1,7}, \hat{\beta}_{1,8}, \ldots, \hat{\beta}_{1,80}$) are similar to the estimation results of $(\hat{\beta}_{1,4}, \hat{\beta}_{1,5}, \hat{\beta}_{1,6})$ as they are the irrelevant set of predictors. It is seen that the time period $T$ mainly controls the precision of the parameter estimates. This investigation
coincides with the asymptotic theory, developed in Section 4.

In summary, our simulation results show that the proposed $C_p$ criterion works well in selecting the number of common pervasive factors, the number of group-specific pervasive factors, and the set of relevant observable risk factors.

5 Application to Chinese stock markets

There are two stock exchange markets in mainland China: the Shanghai and Shenzhen stock exchanges. In these markets, two types of shares are traded, namely A- and B-shares. Although A- and B-shares are listed and traded in the mainland market, the former are denominated in RMB and were originally traded only among Chinese citizens, whereas the latter are denominated in foreign currencies and were originally traded among non-Chinese citizens or Chinese residing overseas. The Chinese government launched the qualified foreign institutional investors (QFII) policy in 2003 and introduced foreign investors into the domestic A-share market. Although Chinese mainlanders have been eligible to trade B-shares with legal foreign currency accounts since March 2001, the mainlanders may prefer to trade only in A-shares owing to the currency barrier. It therefore seems plausible that the underlying asset return structure of A-shares is different from that of B-shares. It is also important to know how these two stock exchange markets respond to the global economy. This paper investigates empirical questions such as the following: How many common and group-specific pervasive factors exist in the stock market in mainland China? What type of observable risk factors explain the market? And, how can the unobservable common factors be understood in terms of observable variables in the economy?

5.1 The Data

We use monthly excess returns of Chinese A- and B-shares from Standard & Poor (S&P)'s Datastream Database. We consider a roughly 11-year sample, covering the
March 2002 to December 2012 period, and systematically exclude stocks with missing returns data. We calculate excess returns by subtracting the interest rate on the one-month interbank offered rate from the individual stock returns. Ideally, we would use the one-month Treasury bill rate instead of the interbank offered rate. However, the one-month Treasury bill rate is only available from 2007. Our reported results are robust to the analysis of the returns, which are not subtracted by the interest rate on the one-month interbank offered rate. We partition our original universe of stocks into two groups, the first containing A-shares, and the second containing B-shares. This implies that the number of groups is $S = 2$. The above filtering procedure yields 1,039 A-share firms and 102 B-share firms. The average return for A-share stocks is -0.084 over the period with standard deviation 14.496, while the average return for B-share stocks is -0.096 with standard deviation 14.03. The A-share market is the main market on the China mainland with a much higher number of stocks. The volatility of stocks on the A- and B-share markets are comparable.

Numerous studies have analyzed stock market reactions of the developed countries to changes in macroeconomic variables (Mandelker and Tandon, 1985; Chen et al., 1986; Cheung and Ng, 1998). If the economic outlook reflects the stock market, such information would be helpful for capturing the stock return performance. With a view that the effective investment style will change over time, it has become more common to consider a variety of types of economic information. Therefore, for the observable risk factors, we employed several types of macroeconomic variables, including macroeconomic climate indexes (leading, coincident, and lagging indexes), the money supply, and the inflation rate (the consumer price index). Monetary policy may affect stock prices (Thorbeke, 1997) through at least two channels. Generally, the growth of the money supply is positively related to the inflation rate. An increase in the money supply may lead to an increase in the inflation rate, which may increase the nominal risk-free interest rate (with the real interest rate being fixed), resulting in a negative
relationship between the money supply and stock prices. This is because the higher discount rate level lowers the value of the firm through the valuation formula. On the other hand, a corporate earning effect may result in increased future cash flow and stock prices, while the effect of a higher discount rate would be neutralized if cash flows increase with inflation. Also, investors would expect higher dividend payments and hence increase their demand for the stocks. Inflation may also be caused through real factors such as consumption. In Marshall (1992), an expected increase in inflation decreases the expected return to money, and this reduces demand for money and increases the demand for equity, resulting in a positive correlation between inflation and stock prices. On the other hand, there are empirical studies (Geske and Roll, 1983) that report a negative relationship between inflation and stock prices.

Commodity prices are a major cost factor in various economic activities in China. Therefore, commodity price information is used for the observable risk factors, including the industrial metal price, the aluminum price, the copper price, the crude oil price, the natural gas price, and the nickel price. In addition to these, we use the gold price and the silver price, which affect the price of alternatives to the traditional financial instruments, including stocks and bonds.

Currency movements directly affect the earnings of Chinese firms. There is an exchange rate risk for holding foreign currency. Also, the value of a firm’s assets with foreign operations, and its revenue through exports, will be affected by fluctuations in exchange rates. Moreover, the firms that sell goods that compete with imports are subject to the price elasticity of consumer demand and impacted by the cost of imported raw materials. In this paper, we consider the Chinese yuan to the US dollar exchange rate, the Chinese yuan to the Japanese yen, the euro, the UK pound, and to the HK dollar exchange rates.

Finally, the international stock market conditions may affect the China mainland stock market. Therefore, we use the S&P 500 index, the MSCI World index, the FTSE
100 index, the MSCI Europe index, the TOPIX index, the Hang Seng index, as well as the MSCI China index. Table 3 provides descriptive statistics of the monthly returns of the above-mentioned observable risk factors. Some observable risk factors are highly skewed. Also, we can see that some variables have heavier tails than normal as their kurtosis levels are above 3.

Figure 1 shows the correlation matrix of the set of 25 observable risk factors. The ordering of the variables in the correlation matrix is identical to the ordering of those in Table 3. The plot indicates that the set of six stock market indexes (S&P 500, MSCI World, FTSE 100, MSCI Europe, TOPIX, Hang Seng, MSCI China) are highly correlated. This implies that the stock markets seem to be connected to each other. Figure 1 also shows that some commodity prices (industrial metal, aluminum, copper, crude oil, nickel) have a high level of correlation. Furthermore, the Chinese yuan to the Japanese yen exchange rate is negatively correlated with some commodity prices (industrial metal, aluminum, copper) as well as with some stock market indexes (S&P 500, MSCI World, FTSE 100, TOPIX). The MSCI World index is correlated with many other variables, with the exception of the China money supply, the China macroeconomic climate indexes (lagging), the inflation rate (consumer price index), the Chinese yuan to the HK dollar exchange rate, the gold price, and the gas price.

5.2 How many pervasive factors?

We fit model (1) by minimizing the objective function. Then, we applied the proposed model-selection criterion, $C_p$, to select simultaneously the number of common pervasive factors, the number of group-specific pervasive factors, and the size of the regularization parameter $\kappa$. The possible numbers of both common and group-specific pervasive factors range from 0 to 10. Possible candidates for the regularization parameter $\kappa$ are $\kappa = \{10, 1, 0.1, 0.01, 0.001\}$. The estimated numbers of common/group-specific pervasive factors are: $\hat{r} = 2$ common pervasive factors, $\hat{r}_1 = 1$ group-specific pervasive
factors with respect to A-shares, and \( \hat{r}_2 = 3 \) group-specific pervasive factors with respect to B-shares. This suggests that there are at least six pervasive factors in the Chinese mainland stock markets.

We next explore the economic meanings of the six constructed factors. Here, we use the methods in Bai and Ng (2006a). Suppose we observe \( s_t \), the time series of an observable economic variable. We are interested in the relationship between the variable \( s_t \) and the unobservable common/group-specific pervasive factors.

Consider the case where we try to explore the meaning of the common pervasive factors \( f_{c,t} \). As pointed out by Bai and Ng (2006a), one may regress \( \varepsilon_i^c = y_{it} - x_{it}'\hat{\beta}_i - \hat{\beta}_{g_{it}}^\prime \hat{\lambda}_{g_{it},i} \) on \( s_t \) and then use some measure to assess the explanatory power of \( s_t \). However, Bai and Ng (2006a) pointed that this is not a satisfactory test because even if \( s_t \) is exactly equal to one of the elements of the common pervasive factors \( f_{c,t} \), \( s_t \) might still be weakly correlated only with \( \varepsilon_i^c \) if the variance of the idiosyncratic error is large. In this paper, following Bai and Ng (2006a), we regress \( s_t \) on the estimated common pervasive factors \( s_t = \hat{f}_{c,t}'\gamma + \hat{e}_{c,t} \), and then conduct the statistical significance test of the least squared estimate \( \hat{\gamma}_c \). Under \( \sqrt{T}/N \to 0 \), Bai and Ng (2006b) showed that \( \sqrt{T}(\hat{\gamma}_c - \gamma_c) \) is asymptotically normal with zero mean and the covariance matrix \( \Sigma_{\gamma_c} \). A consistent estimator of \( \Sigma_{\gamma_c} \), in our setting, is:

\[
\hat{\Sigma}_{\gamma_c} = \left( \frac{1}{T} \sum_{t=1}^{T} \hat{f}_{c,t}' \hat{f}_{c,t} \right)^{-1} \left( \frac{1}{T} \sum_{t=1}^{T} \hat{e}_{c,t}^2 \hat{f}_{c,t}' \hat{f}_{c,t} \right) \left( \frac{1}{T} \sum_{t=1}^{T} \hat{f}_{c,t}' \hat{f}_{c,t} \right)^{-1} ,
\]

with \( \hat{e}_{c,t} = s_t - \hat{\gamma}_c \hat{f}_{c,t} \). We can implement the same idea for exploring the meaning of the group-specific pervasive factors.

To make a link between the estimated common and group-specific pervasive factors, we considered the following six observable economic/market variables: consumer confidence index in China, the Chicago Board Options Exchange (CBOE) volatility index, market excess returns of A-shares, market excess returns of B-shares, and two factors considered by Fama and French (1993), HML and SMB, but computed using the
Chinese data. Note that the market excess returns (MSCI China index) were already used as an observable risk factor. The consumer confidence index measures consumer confidence, which is defined as the degree of optimism on the state of the economy. The CBOE volatility index is a key measure of market expectations of near-term volatility conveyed by S&P 500 stock index option prices, and has been considered by many to be the world’s premier barometer of investor sentiment and market volatility. Because the market excess returns of A- and B-shares represents the group-specific market factor, it is expected that the estimated group-specific factors relate to these observable risk factors. In particular, the first principal component of the A-share group, corresponding to the largest eigenvalue, is related to the market excess returns of A-shares. A similar argument is made in relation to the B-share market. HML factor accounts for the spread in returns between value and growth stocks, and thus shows the value premium. SMB measures the historic excess returns of small caps over big caps. HML and SMB factors are calculated based on the stock returns of Shanghai and Shenzhen stock exchanges. Except for the CBOE volatility index, these 6 variables are from market data in China.

Table 4 summarizes the results. Here, we standardized each of the observable economic/market variables $s_t$ before we regressed them on the estimated factors. In Table 4, for each factor, the first row corresponds to the estimated regression coefficients, whereas the second and third rows correspond to their standard deviations and $t$-values, respectively. If the absolute value of the $t$-value is above 2.56, 1.96, or 1.64, the estimated regression coefficient is statistically significant at 1%, 5% and 10% level, respectively. Table 4 shows that the first common pervasive factor, the first element of $f_{c,t}$, is relating to the market excess returns of A-shares, the market excess returns of B-shares, and the size factor, SMB. The second common pervasive factor is also relating to SMB. Contrary to findings for the US market, the book-to-market ratio is not included in the common pervasive factors across group. However, as shown in the
result for Group B, the third group-specific factor of B-share is relating to HML at the 10% level. This implies that HML factor is effective in the B-share market only. As expected, the first group-specific factor of the B-share market relates strongly to the market excess returns of B-shares. However, none of the six observable factors relate to the first group-specific factor of the A-shares. It would be an interesting topic to investigate what type of economic/market variables relate to the first group-specific factor of A-shares. This also applies to the second group-specific factor of B-shares. With respect to two of the market risk factors (VIX and CCI, explained below), we could not find the relationships with the estimated factors.

### 5.3 What types of observable risk factors explain the market?

From Theorem 2, we can implement a statistical significance test for the estimated beta coefficients, testing whether the regression coefficients $\hat{\beta}_i$ for each security are statistically significant. Table 5 shows the percentage of statistically significant conclusions for each of the observable risk factors. The percentage for the $k$-th observable risk factor is calculated as follows:

$$\frac{1}{N_g} \sum_{i:g_i=g} I\{\hat{\beta}_{ik} \text{ is statistically significant}\},$$

where $I(\cdot)$ is the indicator function, which takes a value of 1 if it is true and 0 otherwise, and $N_g$ is the size of group $g$. The significance level was set at $\alpha = 0.05$. Inspecting Table 5 leads to the following observations. First, among the five Chinese macroeconomic variables, the leading indicator of the macroeconomic climate index, the money supply, and the lagging indicator of the macroeconomic climate index are important in explaining the excess returns of individual stocks both in the A- and B-share markets. On the other hand, the consumer price index does not seem to explain the excess returns of individual stocks during the March 2002 to December 2012 period.

Second, the exchange rate of the Chinese yuan to the UK pound has a large impact on the excess returns of individual stocks in the A-share market. Interestingly, its
explanatory power in relation to B-shares, as indicated by the percentage in Table 5, is half of the power for A-shares. This implies that the investors in B-shares are greatly concerned with the exchange rate of the Chinese yuan to the UK pound. Although they are smaller than the percentage for the Chinese yuan to the UK pound, the percentages in the table for the exchange rates of the Chinese yuan to the US dollar and the Japanese yen are an important source of A- and B-share market fluctuations. Again, the impact of these exchange rates on the A-share market is half of that on the B-share market.

Third, the commodity prices are important observable risk factors. Some contrasts between the A- and B-share markets are interesting. The gold and silver price indexes appear to be more important for A-share investors than they are for B-share investors. On the other hand, the metal, oil, and aluminum price indexes seem to be more important for B-share investors than A-share investors.

Fourth, Table 5 shows that the MSCI China index is important for almost all B-shares, but the index is less important for about half of the A-shares. The MSCI China index consists of securities of B, H, Red Chip and P Chip share classes, but excludes securities of A-share class. Also, the correlation between the market excess returns of A- and B-shares is above 0.8. This may be a reason why half of the A-shares are explained by the MSCI China index, even though the index excludes A-share securities. Also, as shown in Table 4, the first unobserved common factor is highly correlated with the Chinese market excess return, and thus for interpretation, we regard the first unobserved factor as the market excess return.

Fifth, the B-share market participants are more concerned with the FTSE 100 index than are the A-share market participants. The impact of the European, Hong Kong, and Japanese stock markets appears to be less important than that of the China mainland, the US and the UK stock markets for the B-share market participants. Although the European, Hong Kong, and Japanese stock market indexes are not included in
almost all \( \beta_i \)'s, this does not imply that these markets are irrelevant. As shown in Figure 1, the six stock market indexes (S&P 500, MSCI World, FTSE 100, MSCI Europe, TOPIX, Hang Seng, MSCI China) are highly correlated and, thus, some of the indexes are sufficient to explain the variations of individual stock returns of A- and B-shares. Similar arguments apply to the other group of observable risk factors.

5.4 Price of risk

In the APT framework, the expected returns on assets are approximatively linear in their sensitivities to the factors \( E[r] = \nu_0 + \lambda' \nu \), where \( \nu_0 \) is a constant, \( \nu \) is a vector of factor risk premiums, and \( \lambda \) is a vector of factor sensitivities. Here, we partition the excess returns into two groups (A-shares and B-shares) and investigate the subset pricing relations based on Fama and MacBeth (1973) type approach. Two stage approach was also used in Goyal et al. (2008), in which the factor structure of excess returns on stocks traded on the NYSE and Nasdaq (two groups) were studied. Through the model construction process, we have already obtained the matrix of factor sensitivities \( \hat{\Lambda}_c \) (common pervasive factors), \( \hat{\Lambda}_1 \) (group-specific pervasive factors with respect to A-shares), and \( \hat{\Lambda}_2 \) (group-specific pervasive factors with respect to B-shares).

We then run the following cross-sectional regression for each group:

\[
\hat{r}_g = \nu_{0,g} \mathbf{1} + \hat{\Lambda}_c \nu_{G,g} + \hat{\Lambda}_g \nu_g + \hat{\Lambda}_{FF3,g} \nu_{FF3,g} + \xi_g, \quad (g = 1, 2),
\]

where \( \mathbf{1} \) is a vector of ones, \( \xi_g \) is a vector of pricing errors, \( \hat{\Lambda}_{FF3,1} \) is the matrix of sensitivities to the Fama and French’s 3 factors for A-shares (i.e., ER-A, HML, SMB in Table 4), \( \hat{\Lambda}_{FF3,2} \) is the matrix of sensitivities to the Fama and French’s 3 factors for B-shares (i.e., ER-B, HML, SMB in Table 4), and \( \hat{r}_g \) is a vector of average excess returns, which are observable-risk adjusted, i.e., for the \( i \)-th security, \( T^{-1} \sum_{t=1}^{T} (y_{it} - x_{it}' \hat{\beta}_i) \) is used. Here \( x_{it} \) are listed in Table 3 and do not include HML, SMB, ER-A and ER-B factors. Table 6 reports the results of this cross-sectional regression. The estimates for the risk premium on the common-pervasive factors are statistically significant in each
group. Almost all factors seem to be priced. This indicates that our method extracted useful factors that are priced.

One of the main contributions of this paper is to propose a procedure to select the set of relevant observable risk factors. It is also interesting to see whether these selected observable risk factors are priced in the cross-section of asset returns. Similar to the above analysis, we run the following cross-sectional regression for each group:

$$\hat{r}_g = \nu_{0,g} \mathbf{1} + \hat{\Lambda}_{\beta,g} \nu_{\beta,g} + \hat{\Lambda}_{FF3,g} \nu_{FF3,g} + \xi_g, \quad (g = 1, 2),$$

where $\mathbf{1}$ is a vector of ones, $\hat{\Lambda}_{\beta,1}$ is the matrix of sensitivities to the set of observable risk factors for A-shares in Table 5, $\hat{\Lambda}_{\beta,2}$ is the matrix of sensitivities to the set of observable risk factors for B-shares in Table 5, and $\hat{r}_g$ is a vector of average excess returns, which are unobservable common/group-specific pervasive factor adjusted, i.e., for the $i$-th security, $T^{-1} \sum_{t=1}^{T} (y_{it} - \hat{f}'_{c,i} \hat{\lambda}_{c,i} - \hat{f}'_{g,i} \hat{\lambda}_{g,i})$ is used. Table 7 reports the results of this cross-sectional regression. The statistically significant estimates for the risk premium on the observable risk factors varies over the groups. We can see that the estimates on the macroeconomic climate coincident index, Yuan/Yen exchange rate, natural gas, are priced in both groups.

The number of priced observable risk factors for the A-shares market is much greater than for the B-shares market. Together with the number of priced factors of unobservables, the results imply that the A-shares market exhibits more heterogeneity than the B-shares market in terms of the price of risk. Historically, A-shares market investors were mainlanders until 2003. Due to the entry of the qualified foreign institutional investors into the domestic A-share market, the degree of heterogeneity has been increased as the A-share market consists of mainlanders and newly entered foreign investors after 2003. On the other hand, due to the currency barrier of the mainlanders, the investors in B-shares market are still foreign investors. This might be one of the reasons why such differences are observed.
5.5 Robustness check

A unique feature of the Chinese stock market is that many companies issue “twin” A and B shares. Here, the “twin” share has two classes of common shares with identical voting and dividend rights, listed on the same exchanges (Shanghai or Shenzhen stock exchanges), but traded by different participants (see, for instance, Mei et al. (2009)). The dataset contains 50 “twin” A and B shares. To check the robustness of the obtained result, we exclude the 50 “twin” A shares from the dataset, resulting in 989 A-share firms and 102 B-share firms. We then implement the same model construction procedure as in the previous section. The selected numbers of common/group-specific pervasive factors are identical to the case of without excluding the “twin” A shares. Also, similar results are obtained with respect to the observable risk factors. This suggests that the previous results are robust to the presence of twin shares.

The effect from foreign denominated currencies is another market characteristic to be investigated. B-shares are denominated in foreign currencies with Shanghai B-shares traded in U.S. dollars while Shenzhen B-shares in Hong Kong dollars. In the previous section, we analyzed B-shares based on the foreign-currency denominated returns. Here, we take the effect of exchange rates into account. More specifically, we express the B-share returns in Chinese yuan, and then implement the the same model construction procedure as in the previous sections. We use the same dataset without excluding the “twin” A shares. Again, the previously reported results are robust to this change. This is not surprising because the dataset covers a time period in which the value of Chinese yuan was pegged to the U.S. dollar. Although Chinese yuan exchange rate has been allowed to float since 2005, it was in a narrow margin around a fixed base rate determined with reference to a basket of world currencies.
6 Conclusion

We proposed a new econometric modeling procedure for the multifactor asset-pricing model, which has three main features: high-dimensional observable risk factors, unobservable common pervasive factors that influence a large number of assets, and group-specific pervasive factors that influence a subset of assets. Both the number of assets can be much larger than the number of time periods. The number of potential observable risk factors can also be very large owing to the penalization method. We developed a procedure to identify the relevant observable factors from a large number of potentially related factors. We showed that the proposed procedure delivers consistent estimation of the unknown beta coefficients; the estimated beta coefficients are also asymptotically normal. The analysis is nonstandard because of the selection problem in the presence of unobservable factors and a large number of observable factors.

We also studied how to determine the number of (unobservable) common factors and the number of group-specific factors. Monte Carlo simulations demonstrated that the proposed modeling procedure performs well.

We then applied the proposed method to the analysis of the Chinese stock markets and presented a number of empirical findings. Application of the method to the A-share and B-share markets identifies the commonalities and differences in the return structure of the assets across the two markets. The study revealed that the observable risk factors affect the two markets in different ways. The study further demonstrated the existence of two common pervasive factors across the two markets, a single group-specific factor in the A-share market, and three group-specific factors in the B-share market. We also studied the price of risk in the cross section of returns. The findings are robust to the presence of “twin” shares, and robust to the exchange rate fluctuations.
Appendix

A1. Assumptions

We first state the assumptions needed for the asymptotic analysis. Following each assumption, its meaning is briefly explained.

Assumption A: Common/group-specific pervasive factors

The common and group-specific pervasive factors satisfy \( E\|f_{c,t}\|^4 < \infty \) and \( E\|f_{g,t}\|^4 < \infty \) \((g = 1, ..., G)\), respectively. Also

\[
T^{-1} \sum_{t=1}^{T} f_{c,t} f_{c,t}' \to \Sigma_{F_c} \quad \text{and} \quad T^{-1} \sum_{t=1}^{T} f_{g,t} f_{g,t}' \to \Sigma_{F_g}
\]
as \( T \to \infty \), where \( \Sigma_{F_c} \) is an \( r \times r \) positive definite matrix, and \( \Sigma_{F_g} \) is an \( r_g \times r_g \) positive definite matrix. The vector of common/group-specific factor \( f = (f'_{c,t}, f'_{1,t}, ..., f'_{G,t})' \) has a positive definite covariance matrix. Also, we assume orthogonality between the common and group-specific factors \( \frac{1}{T} \sum_{t=1}^{T} f_{c,t} f_{g,t}' = 0 \).

The full rank assumption of \( \Sigma_{F_c} \) and \( \Sigma_{F_g} \) is necessary for the number of common factors to be \( r \) and the number of group-specific factors to be \( r_g \) \((g = 1, 2, ..., G)\). The Assumption B below is for the same reason. The last part of the assumption A assumes that the common factors \( f_{c,t} \) and the group-specific factors \( f_{g,t} \) are orthogonal. Wang (2010) demonstrates that this assumption is needed to separately identify the common (global) and the group-specific factors. However, it can be shown that the estimated slope coefficients \( \beta_i \) does not depend on this assumption.

Assumption B: Factor loadings

The factor-loading matrix for the common pervasive factors \( \Lambda_c = [\lambda_{c,1}, ..., \lambda_{c,N}]' \) satisfies \( E\|\Lambda_{c,i}\|^4 < \infty \) and:

\[
\|N^{-1/2} \Lambda_{c}' \Lambda_c - \Sigma_{\Lambda_c}\| \to 0 \quad \text{as} \quad N \to \infty,
\]

where \( \Sigma_{\Lambda_c} \) is an \( r \times r \) positive definite matrix. Let \( \Lambda_g \) denote the \( N_g \times r \) factor loading matrix for the group factor \( f_{g,t} \) (for assets belong to group \( g \)). For example, if the first...
\(N_1\) assets belong to group 1, then \(\Lambda_1 = [\lambda_{1,1}, \lambda_{1,2}, \ldots, \lambda_{1,N_1}]'\). We assume \(E\|\lambda_{g,i}'\| < \infty\) and
\[
\|N_g^{-1}\Lambda_g' \Lambda_g - \Sigma_{\Lambda_g}\| \to 0 \quad \text{as} \quad N_g \to \infty,
\]
where \(\Sigma_{\Lambda_g}\) is an \(r_g \times r_g\) positive definite matrix, \(g = 1, ..., G\). In addition, \([\Lambda_{cg}, \Lambda_g]\) is of full column rank, where \(\Lambda_{cg}\) consists of rows of \(\Lambda_c\) corresponding to group \(g\).

**Assumption C: Security-specific returns**

There exists a positive constant \(C < \infty\) such that for all \(N\) and \(T\),

(C1): \(E[\varepsilon_{it}] = 0, \ E[|\varepsilon_{it}|^8] < C\) for all \(i\) and \(t\);

(C2): \(E[\varepsilon_{it}\varepsilon_{js}] = \tau_{ij,ts} \) with \(|\tau_{ij,ts}| \leq |\tau_{ij}|\) for some \(\tau_{ij}\) for all \((t,s)\), and \(N^{-1} \sum_{i,j=1}^{N} |\tau_{ij}| < C\); and \(|\tau_{ij,ts}| \leq |\eta_{ts}|\) for some \(\eta_{ts}\) for all \((i,j)\), and \(T^{-1} \sum_{t,s=1}^{T} |\eta_{ts}| < C\). In addition,

\[(TN)^{-1} \sum_{i,j,t,s=1}^{T} |\tau_{ij,ts}| < C\].

(C3): For every \((s,t)\), \(E[|N^{-1/2} \sum_{i=1}^{N} (\varepsilon_{is}\varepsilon_{it} - E[\varepsilon_{is}\varepsilon_{it}])|^4] < C\).

(C4): \(T^{-2}N^{-1} \sum_{t,s,u,v} \sum_{i,j} |\text{cov}(\varepsilon_{is}\varepsilon_{it}, \varepsilon_{ju}\varepsilon_{jv})| < C\) and
\[T^{-1}N^{-2} \sum_{t,s} \sum_{i,j,k,l} \sum_{u,v} |\text{cov}(\varepsilon_{is}\varepsilon_{it}, \varepsilon_{ks}\varepsilon_{lt})| < C\].

(C5): \(\varepsilon_{it}\) is independent of \(x_{js}, \lambda_{c,i}, \lambda_{g,i}, f_{c,a}\) and \(f_{g,s}\) for all \(i,j,t,s,g\).

Assumption C is used in Bai (2003, 2009) and others. These assumptions permit cross-sectional and serial correlations and heteroskedasticities in the idiosyncratic errors. It can be shown that if the \(\varepsilon_{it}\) are independent and have bounded eighth moment, then this assumption holds. The finite eighth moment is a technical assumption and is for theoretical proofs. Simulations show that the method performs well without a finite eighth moment (e.g., student-t distribution with five degrees of freedom).

**Assumption D: Observable risk factors**

We assume \(E\|x_{it}\|^4 < C\). Let \(X_{i,\beta_0 \neq 0}\) be the submatrix of \(X_i\), corresponding to the columns of nonzero elements of the true parameter vector \(\beta_0^i\). We use \(q_i\) to denote the number of nonzero elements of \(\beta_0^i\). Suppose that the \(i\)-th security belongs to the \(g\)-th group (i.e., \(g_i = g\)). We assume the \(q_i \times q_i\) matrix
\[
\frac{1}{T} \left[ X_{i,\beta_0 \neq 0}' M_{F_g, F_g} X_{i,\beta_0 \neq 0} \right]
\]
is positive definite, where\( M_{F_c,F_g} = M_{F_c} - M_{F_c}F_g(F_g' M_{F_c}F_g)^{-1}F_g' M_{F_c} = M_{F_c} - M_{F_c}P_{F_g} M_{F_c}, \)
\( M_{F_c} = I - F_c (F_c F_c')^{-1} F_c', P_{F_g} = F_g (F_g' F_g)^{-1} F_g', \) and\( M_{F_g,F_c} \) is equal to\( M_{F_c,F_g} \) when evaluated at the true common and group-specific factors\( (F_c^0, F_g^0). \)

Also, we define

\[
C_i = (C_{ci}, C_{gi}), \quad B_i = \begin{pmatrix} B_{ci} & B_{cgi} \\ B_{ci}' & B_{gi} \end{pmatrix},
\]

with \( A_i = \frac{1}{T} X_i' M_{F_c,F_g} X_i, B_{ci} = (\lambda_{ci} X_{ci}) \otimes I_T, B_{gi} = (\lambda_{gi} X_{gi}) \otimes I_T, B_{cgi} = (\lambda_{ci} X_{gi}) \otimes I_T, C_{ci} = \frac{1}{\sqrt{T}} X_{ci} \otimes (X_i' M_{F_c,F_g}), C_{gi} = \frac{1}{\sqrt{T}} X_{gi} \otimes (X_i' M_{F_c,F_g}). \) Let \( \mathcal{A} \) be the collection of\( (F_c, F_g) \) such that \( \mathcal{A} = \{(F_c, F_g) : F_c' F_c / T = I, F_g' F_g / T = I\}. \) We assume

\[
\inf_{F_c,F_g \in \mathcal{A}} \left[ \frac{1}{N} \sum_{i: g_i = g} E_i(F_c, F_g) \right] \text{ is positive definite,}
\]

where \( E_i(F_c, F_g) = B_i - C_i'A_i^{-1} C_i \) and \( A_i^{-1} \) is a generalized inverse of \( A_i. \)

A few comments are in order for this assumption. First, we assume the matrix in (10) is positive definite. This is a necessary assumption for consistent estimation of the regression coefficients \( \beta_i \) even if the factors\( (F_c^0, F_g^0) \) are observable. This is the usual rank condition for identification. We do not require the said matrix to be positive definite for all\( (F_c, F_g) \in \mathcal{A} \) (it would not be satisfied). Second, in (11) we require the matrix to be positive definite over \( \mathcal{A}. \) This is used to prove the consistency for the estimates of\( (F_c^0, F_g^0), \) which is unknown; \( \mathcal{A} \) is the parameter space of the factors. We do not require \( A_i \) to be positive definite over \( \mathcal{A}, \) thus a generalized inverse is used. Note that if \( A_i = 0, \) it implies that \( C_i = 0, \) thus \( C_i A_i^{-1} C_i \) is well defined, and in this case, \( E_i = B_i. \) For each\( i, \) the matrix \( E_i \) is semipositive definite. The summation of \( E_i \) over a large number of observations (each group has a large number of securities, see Assumption E below) should be positive definite. Song (2013) assumes that the matrix in (10) is positive definite for all\( (F_c, F_g) \) in our notation (not just for\( (F_c^0, F_g^0), \) which is more difficult to satisfy. Also, he does not consider the regularization problem, nor the co-existence of common and group factors. Our assumption requires a complete new proof of consistency.
Assumption E: Number of securities

This economy is divided into a finite number of groups, $G$, with $g$th group ($g = 1, 2, ..., G$) containing $N_g$ securities such that $0 < a < N_g/N < \bar{a} < 1$, which implies that the number of securities in $g$-th groups will increase as the entire number of securities $N$ grows.

Assumption F: Central limit theory

Let $X_{i,\beta}^0 \neq 0$ be the submatrix of $X_i$ corresponding to columns of nonzero elements of the true parameter vector $\beta^0_i$. We assume the central limit theory

$$
\frac{1}{\sqrt{T}}X'_{i,\beta}^0 M_{F^0_c,F^0_g} \varepsilon_i \rightarrow_d N(0, J_i(F^0_c,F^0_g)),
$$

where $J_i(F^0_c,F^0_g)$ is the probability limit of (as $T$ going to infinity)

$$
\frac{1}{T}X'_{i,\beta}^0 M_{F^0_c,F^0_g} E[\varepsilon_i \varepsilon_i'] M_{F^0_c,F^0_g} X_{i,\beta}^0.
$$

This assumption is required for the asymptotic normality of the estimated $\beta_i$.

Assumption G: Let $\Omega_{k\ell} = E[\varepsilon_k \varepsilon_{\ell}']$. We assume that

$$
B_{NT,i} = \frac{1}{N^2 T} \sum_{k \neq i} \sum_{\ell \neq i} X_k' M_{F^0_c,F^0_g} \Omega_{k\ell} M_{F^0_c,F^0_g} X_\ell = o_p(1).
$$

This assumption holds trivially if $\varepsilon_{it}$ are i.i.d over $i$ and $t$ because $\Omega_{kk} = \sigma^2_k I$ and $\Omega_{k\ell} = 0$ ($k \neq \ell$) and $B_{NT,i}$ reduces to $B_{NT,i} = \frac{1}{N^2 T} \sum_{k \neq i} \sigma^2_k X_k' M_{F^0_c,F^0_g} X_k = O_p(1/N) = o_p(1)$. Cross-sectional independence (without i.i.d) leads to $\Omega_{k\ell} = 0$ ($k \neq \ell$), and $B_{NT,i} = \frac{1}{N^2 T} \sum_{k \neq i} X_k' M_{F^0_c,F^0_g} \Omega_{kk} M_{F^0_c,F^0_g} X_k$, which can also be shown to be $O_p(1/N)$, thus $o_p(1)$. Assumption G still allows weak cross-sectional dependence and serial correlations in $\varepsilon_{it}$. This is a easy to satisfy assumption.

A2. Proof of Theorem 1

We first consider an alternative expression for the objective function in (3). Concentrating out $\Lambda_c$, and substituting $y_i - X_i \beta_i - F_g \lambda_i$ for $w_{c,i}$, (3) is equal to (ignore the
penalty term)

\[
\sum_{g=1}^{G} \sum_{i: g_i = g} (y_i - X_i \beta_i - F_{g_i} \lambda_{g_i,i})' M_{F_c} (y_i - X_i \beta_i - F_{g_i} \lambda_{g_i,i}) \\
= \sum_{g=1}^{G} \text{tr} \left\{ (W_{\beta g} - F_{g} \Lambda'_{g})' M_{F_c} (W_{\beta g} - F_{g} \Lambda'_{g}) \right\},
\]

where \(M_{F_c} = I - F_c (F'_c F_c)^{-1} F'_c = I - F_c F'_c / T\). Here, we denote \(W_{\beta g}\) as the \(T \times N_g\) matrix such that each column consists of \(w_i = y_i - X_i \beta_i\) for all \(i\) in group \(g\). By further concentrating out \(\Lambda_g\) with \(\Lambda_g = W_{\beta g} M_{F_c} F_{g} (F'_g M_{F_c} F_g)^{-1} F'_g M_{F_c} W_{\beta g}\), the above objective function becomes:

\[
\sum_{g=1}^{G} \text{tr} \left\{ W'_{\beta g} (I - M_{F_c} F_g (F'_g M_{F_c} F_g)^{-1} F'_g) M_{F_c} (I - F_g (F'_g M_{F_c} F_g)^{-1} F'_g M_{F_c}) W_{\beta g} \right\},
\]

\[
= \sum_{g=1}^{G} \text{tr} \left\{ W'_{\beta g} M_{F_c} W_{\beta g} \right\} - \text{tr} \left\{ W'_{\beta g} M_{F_c} F_g (F'_g M_{F_c} F_g)^{-1} F'_g M_{F_c} W_{\beta g} \right\},
\]

\[
= \sum_{g=1}^{G} \text{tr} \left\{ W'_{\beta g} M_{F_c,F_g} W_{\beta g} \right\},
\]

where \(M_{F_c,F_g} = M_{F_c} - M_{F_c} F_g (F'_g M_{F_c} F_g)^{-1} F'_g\).

In summary, the true parameters \(\{\beta_1, ..., \beta_N\}, F'_c, F'_g\) and \(\{F'_0, ..., F'_G\}\) are obtained by minimizing the following concentrated (and also centered objective function):

\[
S_{NT}(\beta_1, ..., \beta_N, F_c, F_{1}, ..., F_{G})
= \sum_{g=1}^{G} \text{tr} \left\{ W'_{\beta g} M_{F_c,F_g} W_{\beta g} \right\} + T \sum_{i=1}^{N} p_{k,\gamma} (|\beta_i|) - \sum_{g=1}^{G} \sum_{i: g_i = g} e'_i M_{F_c,F_g} e_i
\]

(12)

The last term is for the purpose of centering, it does not involve unknown parameters. This alternative expression of the objective function is useful for proofing the consistency of the estimated parameters.

The proof extends the that of Bai (2009) to heterogeneous regression coefficients (\(\beta_i\) is not restricted to be common) and to the presence of group-specific factors. Without loss of generality, we assume that \(\beta_i^0 = 0, i = 1, ..., N\) (for notational simplicity). Noting that the true data generating process is \(y_i = F'_c \lambda_{c,i} + F'_g \lambda_{g,i} + \varepsilon_i\)
\(X_i \beta_i^0 = 0\), we have

\[
\frac{1}{NT} S_{NT}(\beta_1, \ldots, \beta_N, F_c, F_1, \ldots, F_G)
\]

\[
= \frac{1}{NT} \sum_{g=1}^{G} \sum_{i: g_i = g} \beta_i' X_i' M_{F_c, F_g} X_i \beta_i + \frac{2}{NT} \sum_{g=1}^{G} \sum_{i: g_i = g} \beta_i' X_i' M_{F_c, F_g} F_c^0 \lambda_{c,i}
\]

\[
+ \frac{2}{NT} \sum_{g=1}^{G} \sum_{i: g_i = g} \beta_i' X_i' M_{F_c, F_g} F_g^0 \lambda_{g,i} + \frac{1}{NT} \sum_{g=1}^{G} \sum_{i: g_i = g} \lambda_{c,i} F_c^0 M_{F_c, F_g} F_c^0 \lambda_{c,i}
\]

\[
+ \frac{2}{NT} \sum_{g=1}^{G} \sum_{i: g_i = g} \lambda_{c,i} F_c^0 M_{F_c, F_g} F_g^0 \lambda_{g,i} + \frac{1}{NT} \sum_{g=1}^{G} \sum_{i: g_i = g} \lambda_{g,i} F_g^0 M_{F_c, F_g} F_g^0 \lambda_{g,i}
\]

\[
+ \frac{2}{NT} \sum_{g=1}^{G} \sum_{i: g_i = g} \lambda_{c,i} F_c^0 M_{F_c, F_g} \varepsilon_i + \frac{2}{NT} \sum_{g=1}^{G} \sum_{i: g_i = g} (F_c^0 \lambda_{c,i})' M_{F_c, F_g} \varepsilon_i
\]

\[
+ \frac{1}{NT} \sum_{g=1}^{G} \sum_{i: g_i = g} \varepsilon_i (M_{F_c, F_g} - M_{F_c, F_g}^0) \varepsilon_i + \frac{2}{NT} \sum_{g=1}^{G} \sum_{i: g_i = g} (F_g^0 \lambda_{g,i})' M_{F_c, F_g} \varepsilon_i
\]

\[
+ \frac{1}{N} \sum_{i=1}^{N} \rho_{n, \gamma} (|\beta_i|)
\]

where \(\Lambda_{cg} (N_g \times r)\) consists of the factor loadings associated with the common factor \((f_c)\) with respect to the \(g\)-th group. We can show that terms involving \(\varepsilon_i\) are \(o_p(1)\), that is

\[
\frac{1}{NT} \sum_{g=1}^{G} \sum_{i: g_i = g} \beta_i' X_i' M_{F_c, F_g} \varepsilon_i = o_p(1),
\]

\[
\frac{1}{NT} \sum_{g=1}^{G} \sum_{i: g_i = g} (F_c^0 \lambda_{c,i})' M_{F_c, F_g} \varepsilon_i = o_p(1),
\]

\[
\frac{1}{NT} \sum_{g=1}^{G} \sum_{i: g_i = g} \varepsilon_i (M_{F_c, F_g} - M_{F_c, F_g}^0) \varepsilon_i = o_p(1),
\]

\[
\frac{1}{NT} \sum_{g=1}^{G} \sum_{i: g_i = g} (F_g^0 \lambda_{g,i})' M_{F_c, F_g} \varepsilon_i = o_p(1),
\]

where \(o_p(1)\) holds uniformly over \(||\beta_i|| \leq C\), and uniformly over \(F_c\) and \(F_g\) such that \(F_c^0 F_c / T = I_r\) and \(F_g^0 F_g / T = I_{r_g}\). This follows from Lemma A1 of Bai (2009). Thus the first six terms in the \(S_{NT}\) dominates the next four terms. Let

\[
\frac{1}{NT} S_{NT}(\beta_1, \ldots, \beta_N, F_c, F_1, \ldots, F_G)
\]

47
denote the first six terms in $\frac{1}{NT}S_{NT}$. Note that the term $\frac{1}{N} \sum_{i=1}^{N} \| \beta_i \|$ is $o_p(1)$ from the assumption on the regularization parameter. We can rewrite

$$
\frac{1}{NT} S_{NT}(\beta_1, ..., \beta_N, F_c, F_1, ..., F_G) = \frac{1}{NT} \tilde{S}_{NT}(\beta_1, ..., \beta_N, F_c, F_1, ..., F_G) + o_p(1) \quad (13)
$$

From

$$
F_g^{0'} M_{F_c,F_g} = 0, \quad F_c^{0'} M_{F_c,F_g} = 0,
$$

we have $\tilde{S}_{NT}(\beta_1, ..., \beta_N, F_c^0 H_c, F_1^0 H_1, ..., F_G^0 H_G) = 0$ for any $r \times r$ invertible matrix $H_c$ and the $r_g \times r_g$ invertible matrices $H_g, \ g = 1, \ldots, G$.

Introduce

$$
A_i = \frac{1}{T} X_i' M_{F_c,F_c} X_i, \quad B_{ci} = (\lambda_{ci}, \lambda_{ci}') \odot I_T, \quad B_{gi} = (\lambda_{gi}, \lambda_{gi}') \odot I_T,
$$

$$
B_{cgi} = (\lambda_{ci}, \lambda_{gi}') \odot I_T, \quad C_{ci}' = \frac{1}{\sqrt{T}} \lambda_{ci}' \odot (X_i' M_{F_c,F_c}), \quad C_{gi}' = \frac{1}{\sqrt{T}} \lambda_{gi}' \odot (X_i' M_{F_c,F_c}),
$$

$$
\eta_c = \frac{1}{\sqrt{T}} \text{vec}(M_{F_c,F_c} F_c^0), \quad \eta_g = \frac{1}{\sqrt{T}} \text{vec}(M_{F_c,F_g} F_g^0).
$$

Then

$$
\frac{1}{NT} \tilde{S}_{NT}(\beta_1, ..., \beta_N, F_c, F_1, ..., F_G)
$$

$$
= \frac{1}{N} \sum_{g=1}^{G} \sum_{i:gi=g} \beta_i A_i \beta_i + \frac{2}{N} \sum_{g=1}^{G} \sum_{i:gi=g} \beta_i C_{ci} \eta_c + \frac{2}{N} \sum_{g=1}^{G} \sum_{i:gi=g} \beta_i C_{gi} \eta_g + 
$$

$$
\frac{1}{N} \sum_{g=1}^{G} \sum_{i:gi=g} \eta_c'B_{ci} \eta_c + \frac{2}{N} \sum_{g=1}^{G} \sum_{i:gi=g} \eta_c'B_{cgi} \eta_g + \frac{1}{N} \sum_{g=1}^{G} \sum_{i:gi=g} \eta'_g B_{gi} \eta_g
$$

Completing the square,

$$
\frac{1}{NT} \tilde{S}_{NT}(\beta_1, ..., \beta_N, F_c, F_1, ..., F_G)
$$

$$
= \frac{1}{N} \sum_{g=1}^{G} \sum_{i:gi=g} \beta_i A_i \beta_i + \frac{2}{N} \sum_{g=1}^{G} \sum_{i:gi=g} \beta_i C_{ci} \eta_{c,g} + \frac{1}{N} \sum_{g=1}^{G} \sum_{i:gi=g} \eta'_{c,g} B_{i} \eta_{c,g}
$$

$$
= \sum_{g=1}^{G} \eta'_{c,g} \left( \frac{1}{N} \sum_{i:gi=g} E_i \right) \eta_{c,g} + \frac{1}{N} \sum_{g=1}^{G} \sum_{i:gi=g} (\beta_i + C_{ci} \eta_{c,g})' A_i (\beta_i + C_{ci} \eta_{c,g})
$$

where

$$
C_i = (C_{ci}, C_{gi}), \quad B_i = \begin{pmatrix} B_{ci} & B_{cgi} \\ B_{cgi} & B_{gi} \end{pmatrix}, \quad \eta_{c,g} = (\eta'_c, \eta'_g)',
$$

48
and \( E_i = B_i - C_i' A_i^{-} C_i \) with \( A_i^{-} \) being a generalized inverse of \( A_i \). Note that if \( A_i = 0 \), then \( C_i \) must be zero because \( X_i'M_{c_i}F_g = 0 \). As a result, the term \( C_i' A_i^{-} C_i \) becomes \( C_i' A_i^{-} C_i = 0 \). Thus, \( C_i' A_i^{-} C_i \) is well defined even if \( A_i = 0 \).

Notice that \( \tilde{S}_{NT} \) is quadratic in \( \boldsymbol{n}_{c,g} \) and in \( \beta_i + A_i^{-} C_i \eta_{c,g} \). By Assumption D, \( \frac{1}{N} \sum_{i,g_i=g} E_i \) is positive definite and \( A_i \) is semipositive definite, it follows that

\[
\tilde{S}_{NT}(\beta_1, ..., \beta_N, F_c, F_1, ..., F_G) \geq 0
\]

for all \( (\beta_1, ..., \beta_N, F_c, F_1, ..., F_G) \).

Note that the centered objective function satisfies

\[
\frac{1}{NT} S_{NT}(\beta_1, ..., \beta_N, F_c, F_1, ..., F_G) = \frac{1}{N} \sum_{i=1}^{N} p_{\kappa,\gamma} (|\beta_i|) = o_p(1)
\]

here we have used \( \frac{1}{NT} \tilde{S}_{NT}(\beta_1, ..., \beta_N, F_c, F_1, ..., F_G) = 0 \), as noted earlier. Note that

\[
\frac{1}{NT} S_{NT}(\beta_1, ..., \hat{\beta}_N, \hat{F}_c, \hat{F}_1, ..., \hat{F}_G) + \frac{1}{N} \sum_{i=1}^{N} p_{\kappa,\gamma} (|\hat{\beta}_i|)
\leq \frac{1}{NT} S_{NT}(\beta_1, ..., \beta_N, F_c, F_1, ..., F_G) + \frac{1}{N} \sum_{i=1}^{N} p_{\kappa,\gamma} (|\beta_i|) = o_p(1)
\]

by definition of \( \{\hat{\beta}_1, ..., \hat{\beta}_N, \hat{F}_c, \hat{F}_1, ..., \hat{F}_G\} \). Because the penalties terms are \( o_p(1) \) we have

\[
o_p(1) \geq \frac{1}{NT} S_{NT}(\beta_1, ..., \hat{\beta}_N, \hat{F}_c, \hat{F}_1, ..., \hat{F}_G)
= \frac{1}{NT} \tilde{S}_{NT}(\beta_1, ..., \beta_N, F_c, F_1, ..., F_G) + o_p(1).
\]

where the equality follows from (13). Combined with \( \tilde{S}_{NT}(\beta_1, ..., \beta_N, F_c, F_1, ..., F_G) \geq 0 \), it must be true that

\[
\frac{1}{NT} \tilde{S}_{NT}(\beta_1, ..., \beta_N, F_c, F_1, ..., F_G) = o_p(1).
\]

This implies that

\[
\sum_{g=1}^{G} \hat{\eta}_{c,g} \left( \frac{1}{N} \sum_{i:g_i=g} \hat{E}_i \right) \hat{\eta}_{c,g} = o_p(1), \quad (14)
\]

\[
\frac{1}{N} \sum_{g=1}^{G} \sum_{i:g_i=g} \left( \beta_i + A_i^{-} \hat{C}_i \hat{\eta}_{c,g} \right)' A_i \left( \beta_i + A_i^{-} \hat{C}_i \hat{\eta}_{c,g} \right) = o_p(1). \quad (15)
\]
where $\hat{\eta}_{c,g}$, $\hat{A}_i$, $\hat{B}_i$, $\hat{C}_i$, and $\hat{E}_i$ (with $\hat{E}_i = E_i(\hat{F}_c, \hat{F}_g)$) correspond to $\eta_{c,g}$, $A_i$, $B_i$, $C_i$ and $E_i$, all evaluated at the estimates \{$\hat{\beta}_1, ..., \hat{\beta}_N$, $\hat{F}_c$, $\hat{F}_1$, ..., $\hat{F}_G$\}.

From Assumption D, the matrix $N^{-1} \sum_{i;g=g} \hat{E}_i$ is positive definite, and thus equation (14) implies that $\|\hat{\eta}_{c,g}\|^2 = o_p(1)$ for $g = 1, ..., G$. That is, we have proved that

\[
\frac{1}{N} \|M_{\hat{F}_c, \hat{F}_g}(F^0_c, F^0_g)\|^2 = o_p(1)
\]

This result implies that

\[
\|M_{\hat{F}_c, \hat{F}_g} - M_{F^0_c, F^0_g}\| = \|P_{\hat{F}_c, \hat{F}_g} - P_{F^0_c, F^0_g}\| = o_p(1) \quad (16)
\]

See Bai (2009, page 1265). That is, the space spanned by $(F^0_c, F^0_g)$ and the space spanned by the estimated factors $(\hat{F}_c, \hat{F}_g)$ are asymptotically the same. Because the common factors $F_c$ and the group specific factors are orthogonal (Assumption A), the preceding result implies that

\[
\|M_{F^0_c} - M_{F_c}\| = o_p(1), \quad \|M_{F^0_g} - M_{F_g}\| = o_p(1) \quad (17)
\]

We next prove the consistency of $\hat{\beta}_i$. From $\|\hat{\eta}_{c,g}\|^2 = o_p(1)$ for $g = 1, ..., G$, equation (15) implies that

\[
\frac{1}{N} \sum_{g=1}^G \sum_{i;g=g} \hat{\beta}_i' \hat{A}_i \hat{\beta}_i = o_p(1).
\]

This implies an average consistency of $\hat{\beta}_i$, but it does not imply individual consistency for each $i$. We shall use (16) to prove individual consistency. First, note that $\hat{\beta}_i$ satisfies

\[
\hat{\beta}_i = \arg\min_{\beta_i} \left[ \frac{1}{T} (y_i - X_i \beta_i)' M_{\hat{F}_c, \hat{F}_g}(y_i - X_i \beta_i) + p_{\kappa, \gamma}(|\beta_i|) \right] \quad (18)
\]

we have used $M_{\hat{F}_c, \hat{F}_g} \hat{F}_c = 0$ and $M_{\hat{F}_c, \hat{F}_g} \hat{F}_g = 0$. Using (16), we can easily show that

\[
\left| \frac{1}{T} (y_i - X_i \beta_i)' M_{F^0_c, F^0_g}(y_i - X_i \beta_i) - \frac{1}{T} (y_i - X_i \beta_i)' M_{\hat{F}_c, \hat{F}_g}(y_i - X_i \beta_i) \right| = o_p(1). \quad (19)
\]

Let $\tilde{\beta}_i$ be the infeasible estimator defined as

\[
\tilde{\beta}_i = \arg\min_{\beta_i} \left[ \frac{1}{T} (y_i - X_i \beta_i)' M_{F^0_c, F^0_g}(y_i - X_i \beta_i) + p_{\kappa, \gamma}(|\beta_i|) \right] = \arg\min_{\beta_i} \left[ \frac{1}{T} (\tilde{y}_i - X_i \beta_i)' M_{F^0_c, F^0_g}(\tilde{y}_i - X_i \beta_i) + p_{\kappa, \gamma}(|\beta_i|) \right],
\]

50
where $y_i^* = X_i\beta_0^0 + \varepsilon_i$. In view of (19), $\hat{\beta}_i$ and $\tilde{\beta}_i$ are asymptotically equivalent,

$$\|\hat{\beta}_i - \tilde{\beta}_i\| = o_p(1)$$

It remains to show that $\tilde{\beta}_i$ is consistent. Let

$$R_i(\beta_i) = \frac{1}{T}(y_i^* - X_i\beta_i)'M_{F_0}^{-1}F_0(y_i^* - X_i\beta_i) + p_{\kappa,\gamma}(|\beta_i|)$$

and let $\alpha_{iT} = T^{-1/2}d_{iT}$ with $d_{iT} = \max\{p'_{\kappa,\gamma}(|\beta_{ik}^0|); \beta_{ik}^0 \neq 0\}$. Under $\max\{p'_{\kappa,\gamma}(|\beta_{ik}^0|); \beta_{ik}^0 \neq 0\} \to 0$ (which holds for the SCAD considered in this paper), we now show that there exists a local minimizer $\tilde{\beta}_i$ of $R_i(\beta_i)$ such that $\|\hat{\beta}_i - \tilde{\beta}_i\| = O_p(T^{-1/2} + d_{iT})$.

As in Fan and Li (2001), it is enough to show that for any given $\beta_i^0 + \alpha_{iT}u$, there exists a large constant $C$ such that

$$P\left[\min_{\|u\| = C} R_i(\beta_i^0 + \alpha_{iT}u) > R_i(\beta_i^0)\right] \geq 1 - \epsilon,$$

(20)

because with probability at least $1 - \epsilon$ that there exists a local minimum in the ball $\{\beta_i^0 + \alpha_{iT}u; \|u\| \leq C\}$, which implies that there exists a local minimizer such that $\|\hat{\beta}_i - \beta_i^0\| = O_p(\alpha_{iT})$. From $p_{\kappa,\gamma}(0) = 0$, we have

$$R_i(\beta_i^0 + \alpha_{iT}u) - R_i(\beta_i^0) \geq \frac{1}{T}(y_i^* - X_i(\beta_i^0 + \alpha_{iT}u)'M_{F_0}^{-1}F_0(y_i^* - X_i(\beta_i^0 + \alpha_{iT}u))) + \sum_{k=1}^{q_i} p_{\kappa,\gamma}(\|\beta_{ik}^0 + \alpha_{iT}u_k\|)$$

$$- \frac{1}{T}(y_i^* - X_i(\beta_i^0)'M_{F_0}^{-1}F_0(y_i^* - X_i\beta_i^0)) - \sum_{k=1}^{q_i} p_{\kappa,\gamma}(\|\beta_{ik}^0\|)$$

where $q_i$ is the number of components of $\beta_i^0$. By using the Taylor expansion, we have

$$R_i(\beta_i^0 + \alpha_{iT}u) - R_i(\beta_i^0) \geq -2\alpha_{iT} \frac{1}{T}(y_i^* - X_i\beta_i^0)'M_{F_0}^{-1}F_0 X_i u + u' \frac{1}{T} \tilde{X}_i' M_{F_0}^{-1}F_0 \tilde{X}_i u \alpha_{iT}^2 \{1 + o_p(1)\}$$

$$+ \sum_{k=1}^{q_i} \left[ \alpha_{iT} p'_{\kappa,\gamma}(\|\beta_{ik}^0\|) \text{sgn}(\beta_{ik}^0)u_k + \alpha_{iT}^2 p''_{\kappa,\gamma}(\|\beta_{ik}^0\|) u_k^2 \{1 + o_p(1)\} \right],$$

where $\tilde{X}_i$ is $T \times q_i$ matrix that consist of true regressors (with non-zero coefficients), and $\tilde{X}_i' M_{F_0}^{-1}F_0 \tilde{X}_i/T$ is a positive definite matrix from Assumption D. From $\frac{1}{T}(y_i^* - X_i\beta_i^0)'M_{F_0}^{-1}F_0 X_i = \frac{1}{T} \epsilon' M_{F_0}^{-1}F_0 X_i = O_p(T^{-1/2})$, the first term is on the order $O_p(\alpha_{iT} T^{-1/2})\|u\|$.
the second term is on the order $O_p(\alpha_i^2)\|u\|^2$. By choosing a sufficiently large constant $C$, the second term dominates the first term uniformly in $\|u\| = C$. The third term is bounded by $\sqrt{q_i} \alpha_i d_{iT} \|u\| + \alpha_i^2 \max\{p''_{\kappa T, \gamma}(|\beta_{ik}^0|); \beta_{ik}^0 \neq 0\} \|u\|^2$, which is also dominated by the second term. In summary, by choosing a sufficiently large constant $C$, (20) holds. Thus, there exists a local minimizer $\hat{\beta}_i$ of $R_i(\beta_i)$ such that $\|\hat{\beta}_i - \beta_i^0\| = O_p(T^{-1/2} + d_{iT}) = o_p(1)$. Thus the asymptotical equivalence between $\hat{\beta}_i$ and $\tilde{\beta}_i$ implies the consistency of $\hat{\beta}_i$, i.e., for any $\delta > 0$, we have

$$P \left( \|\hat{\beta}_i - \beta_i^0\| > \delta \right) \rightarrow 0, \quad T \rightarrow \infty. \tag{21}$$

Under Assumption A, $F_0^c F_0^c / T$ and $F_0^g F_0^g / T$ converge to positive definite matrices. Using (17) we can further show

$$\frac{1}{\sqrt{T}} \|F_0^c H_c - \hat{F}_c\| = o_p(1), \quad \text{and} \quad \frac{1}{\sqrt{T}} \|F_0^g H_g - \hat{F}_g\| = o_p(1), \quad g = 1, \ldots, G,$n

for some rotation matrices $H_c$ and $H_g$. The details are omitted. This proves Theorem 1. The proofs for the remaining theorems are provided in an online supplement.

[73] Wang, P. 2010. Large dimensional factor models with a multi-level factor structure, unpublished manuscript, Department of Economics, HKUST.

Five different data generating processes (DGP) are considered. The number of common pervasive factors is $r = 5$, and the numbers of group-specific pervasive factors are $r_1 = 2$, $r_2 = 3$, $r_3 = 4$, $r_4 = 4$, and $r_5 = 5$. The sample size for the first panel is $T = 130$, $N = 920$; the second panel is $T = 150$ and $N = 1000$; the third panel is $T = 200$, $N = 1000$.

Table 2: Means and standard deviations (SD) of the estimated regression coefficients. Results are based on 1000 repetitions. Data-generating process 4 is used. Only $\hat{\beta}_1$ (the first cross section) is reported because the theoretical properties of $\hat{\beta}_i$ are common for each $i$. The dimension of $\hat{\beta}_1 = (\hat{\beta}_{1,1}, \ldots, \hat{\beta}_{1,p})'$ is large ($p = 80$). The first three elements of $\hat{\beta}_i$ are nonzero, the rest are zeros. We only report $(\hat{\beta}_{1,1}, \hat{\beta}_{1,2}, \hat{\beta}_{1,3}, \hat{\beta}_{1,4}, \hat{\beta}_{1,5}, \hat{\beta}_{1,6})'$. The remaining elements $\hat{\beta}_{1,7}, \ldots, \hat{\beta}_{1,p}$ have similar properties as $\hat{\beta}_{1,4}, \hat{\beta}_{1,5}, \hat{\beta}_{1,6}$.

Table 4: Regression results when regressing observable risk factors $s_t$ on estimated common and group-specific factors. For example, when we regress $s_t$ on the estimated common pervasive factors $\hat{f}_{c,t}$, the regression model is $s_t = \hat{f}_{c,t} \gamma_c + \epsilon_{c,t}$, where $\gamma_c$ are the regression coefficients, and $\epsilon_{c,t}$ is the error term. The six observable risk factors $s_t$ are the consumer confidence index in China (CCI), the CBOE volatility index (VIX), market excess returns of A-shares (ER–A), market excess returns of B-shares (ER–B), the book-to-market ratio (HML), and the market capitalization (SMB). HML and SMB are based on Chinese stock returns. For each observable factor, the first row corresponds to the estimated regression coefficients $\hat{\gamma}_c$, whereas the second and third rows are the corresponding standard deviations and $t$-values.

Table 5: The percentage of statistically significant observable risk factors across markets. The percentage for the $k$-th observable risk factor is calculated as $\sum_{i_{g_{k}}=g} I\{\hat{\beta}_{ik} \text{ is statistically significant}\}/N_{g}$, where $I(\cdot)$ is the indicator function and $N_{g}$ is the size of group $g$. The significance level was set as $\alpha = 0.05$.

Table 6: Factor risk premiums for the common and group-specific factors and for the Fama-French three factors. There are two common pervasive factors, a single group-specific pervasive factor of A-shares, and three group-specific pervasive factors of B-shares. The Fama and French factors are constructed from the Chinese stock returns. For each group, we run the following cross-sectional regression: $\hat{r}_g = \nu_{0,g} \mathbf{1} + \hat{\Lambda}_c \nu_{c,g} + \hat{\Lambda}_g \nu_g + \hat{\Lambda}_{FF3,g} \nu_{FF3,g} + \xi_g$, ($g = 1, 2$). Details on this model are described in Section 5.4. The first line associated with each row presents the factor risk price estimates, and the second line reports the $p$-value (in parenthesis). The $R^2_{OLS}$ denotes the OLS cross-sectional $R^2$.
