Abstract

We show that credit score heterogeneity dampens monetary policy transmission through fixed-rate mortgages. Using Fannie Mae Single-Family Loan-Level historical data, we show that a 1 percentage point decrease in mortgage rate increases the refinancing probability for borrowers with a FICO credit score of 800 twice as much as that for borrowers with a FICO score of 700. We then develop a refinancing model and find that credit score heterogeneity dampens consumption response to monetary policy by 11%, compared to a standard model with only mortgage rate heterogeneity. Borrowers with lower credit scores have higher marginal propensities to consume and benefit from refinancing more than borrowers with higher credit scores, but refinance less often, resulting in a smaller consumption response.

1 Introduction

Monetary policy can stimulate household consumption and wealth by lowering mortgage costs through refinancing. In the U.S., fixed-rate mortgages (FRMs) are the most significant source of household debt and, therefore, one of the primary mechanisms for monetary policy transmission.¹ Lower interest rates lead FRM holders with rates higher than the current market rate (i.e., positive rate gaps) to refinance.² The consequent decline in mortgage debt payments generates an increase in wealth and consumption.

The extent of monetary policy transmission to FRM refinancing depends not only on the number of mortgages with positive rate gaps, but also on households' willingness and ability to refinance their mortgages. On the one hand, many borrowers refinance sub-optimally; this heterogeneity in refinancing is associated with inattention and demographic characteristics.³ On the other, refinance loans are subject to rigorous underwriting criteria that represent a credit constraint to some borrowers and potentially depend on the state of the economy.⁴ The existence of credit constraints related to underwriting criteria (credit score, for instance) can lead to heterogeneous monetary policy effects because not all borrowers with positive rate gaps can access mortgage markets. This heterogeneity in refinancing opportunities can therefore dampen the effects of monetary policy.

In this paper, we combine empirical patterns from monthly loan-level data and a heterogeneous agent model to show that monetary transmission through the FRM channel is limited because it depends on borrowers' credit score distribution besides their rate gap distribution. The intuition behind this mechanism is: borrowers with lower credit scores have higher marginal propensities to consume (MPCs). They, therefore, benefit from refinancing more than borrowers with higher credit scores, but are less likely or able to refinance their mortgages and borrow unsecured debt. Consequently,

¹Goodman, McCargo, Golding, Parrott, Pardo, Hill, Kaul, Bai, Strochak, Reyes, and Walsh (2019) document that in the U.S., mortgages add up to 65% of all household liabilities and roughly 60% of them have a fixed rate and maturity of 30 years.

²We refer to the difference between the loan outstanding mortgage rate and the current market rate on similar mortgages as a "rate gap."

³See Bhutta and Keys (2016), Johnson, Meier, and Toubia (2019), Agarwal, Ben-David, and Yao (2017), Andersen, Campbell, Nielsen, and Ramadorai (2020), Gerardi, Willen, and Zhang (2020).

⁴Over the last years, the fraction of denied refinance applications was higher than that of denied purchase applications. According to HMDA data, in 2007, banks denied 30% of refinancing and 20% of purchase loan applications; in 2017, those numbers were 19% and 12%, respectively. The main reasons for their denial include bad credit history, high debt-to-income ratio, and low collateral value (high loan-to-value ratio).

the associated change in aggregate consumption in response to monetary policy is lower compared to scenarios where people with the most extensive benefits from refinancing can freely refinance and borrow.

Refinancing heterogeneity in any characteristic will affect aggregate spending only if that characteristic correlates with MPC. The data linking refinancing, borrower characteristics, and spending is limited, making it challenging to estimate the correlation between significant determinants of refinancing and spending. However, borrower's credit score, among their other characteristics, directly relates to their borrowing constraint. Credit score is a crucial and a prohibitive criterion for credit approval. Even if the borrower has access to liquid assets but does not have sufficiently high credit score, the lender will not originate a loan.

To deliver detailed results on credit score heterogeneity of refinance response to monetary policy and motivate a heterogeneous agent model of refinancing, we begin with an empirical analysis using Fannie Mae Single-Family Loan-Level historical data. We estimate that a 1 percentage point increase in the rate gap increases the refinancing probability for borrowers with a FICO credit score of 800 twice as much as that for borrowers with a FICO score of 700. Our refinancing model suggests that this heterogeneity is economically significant – the aggregate consumption response to monetary policy on impact is approximately 11% lower than in a standard model with only mortgage rate heterogeneity.

In the empirical part of the paper, we document credit score heterogeneity of the refinancing response to changes in mortgage rates in three steps. First, we motivate our study of borrowers' credit score heterogeneity by illustrating the connection between credit score distribution and refinancing. Second, we show that, for each rate gap, there are significant differences in the refinancing hazards of borrowers in lower and upper quartile credit score distribution, even after controlling for observable loan characteristics and fine geographic-by-time fixed effects. Credit score heterogeneity is more important than that across other loan characteristics, such as debt-to-income (DTI) and loan-to-value (LTV) ratios. Third, we exploit exogenous changes in monetary policy to measure the marginal effect of credit score heterogeneity on refinancing to avoid bias caused by omitted variables that affect both mortgage rate and refinancing through channels distinct from monetary policy.

To motivate our analysis of credit score heterogeneity, we start with the observation that borrowers with higher credit scores are the ones who refinance most actively, coupled

with the evidence of time-varying credit score distribution. A credit score is the crucial underwriting criterion that affects refinancing opportunities and refinancing. Time-varying credit score distribution suggests that refinancing opportunities change over time. These findings suggest that credit scores are another potential source of refinancing heterogeneity besides rate gap distribution and demographic characteristics documented in the refinancing literature.

Our second step is to show that, for each rate gap, there are significant differences between the fraction of refinancing loans among borrowers in different credit score quartiles. We do so by characterizing the refinancing hazard as a non-parametric function of the rate gap, credit score bin, and other loan characteristics. Pooling observations across time, we sort borrowers into rate gap bins and credit score quartiles and calculate the fraction of refinanced loans in each rate gap bin and credit score quartile. We then show that refinancing hazards for each credit score quartile exhibit a step-like shape: refinancing rates are low and constant among loans with negative rate gaps, and are high and constant among loans with positive rate gaps. However, among mortgages with positive rate gaps, loans with credit scores in the upper quartile have a much higher probability of refinancing than loans in the lower credit score quartile. The difference in refinancing between lower and higher credit score quartiles is robust to excluding loans with high loan-to-value ratios, observations during 2007 – 2011 when households were more likely to be unemployed, and loans with substantial remaining balances.

The credit score heterogeneity in refinancing is significant and larger than that in other borrower characteristics – LTV, DTI, and remaining balance. They are robust to (i) using an alternative definition of rate gap aiming to remove borrower fixed effects, (ii) controlling for payment history rather than remaining balance, (iii) aggregation to quarterly frequency and to a 3-digit ZIP-code level. This result is driven by the episodes of mortgage rate decreases because it is much smaller during cycles of tight monetary policy.

To quantify the effect of the credit score heterogeneity on refinancing, we instrument rate gaps with high-frequency monetary shocks to avoid endogeneity because of confounding factors such as household liquidity constraints during recessions that prevent them from paying refinancing costs. We instrument rate gaps with high-frequency monetary policy shocks. High-frequency identification yields the unexpected part of the monetary policy shock because it controls for the market expectations by taking into account rate changes only within a small window. A 1 percentage point increase in rate

gap leads to a 1.25 percentage point increase in the likelihood of refinancing for borrowers with a credit score of 800. However, this likelihood rises by only 0.54 percentage points for borrowers with a credit score of 700. The marginal impact of a standard deviation increase in credit score amounts to 27% of average monthly refinancing rate.

To show that credit score heterogeneity matters for monetary transmission to aggregate consumption, we build a heterogeneous agent model with FRMs similar to [Berger, Milbradt, Tourre, and Vavra \(2021\)](#). The main experiment is to compare aggregate consumption response to rate cuts in two economies – one where agents have same access to credit markets and one where agents differ in their credit scores which determines their ability to refinance and borrow.

The model features a consumption-savings decision in an incomplete market setting, labor income risk, and refinancing of FRMs. We employ a standard consumption-savings framework with a borrowing constraint. Households face individual labor income risk and aggregate interest rate risk, which plays a role of monetary policy. To that standard setup, we add FRMs. Each household owns a house financed by a mortgage with a refinancing option. Refinancing enters via a Calvo-style exogenous shock – agents refinance at Poisson arrival times only if their rate gap is positive. The Calvo model for refinancing is consistent with the step-like hazard function we observe from the data.

The novel feature of our model is the means by which it integrates credit score heterogeneity in the heterogeneous economy: credit score determines ability to borrow in all credit markets. Intuitively, credit score predicts how likely the borrowers will pay a loan back. If this probability is low, they can neither refinance the mortgage, nor borrow more unsecured debt.

In the economy where agents (exogenously) differ in credit scores, lower credit score borrowers end up exhibiting higher MPCs than higher credit score borrowers because credit score determines borrowing in two ways. First, higher credit score borrowers have a higher probability of receiving the refinancing shock. This assumption is consistent with our main empirical finding and incorporates demand- and supply-side mechanisms behind credit score heterogeneity. For example, higher credit score borrowers might be more attentive to changes in interest rates. Or banks might transmit lower rates only to higher credit score borrowers. Second, higher credit score borrowers have higher borrowing limits on liquid debt.

We demonstrate that the aggregate consumption response to a 1 percentage point decrease in the market mortgage rate is 11% lower in the economy with credit score

heterogeneity compared to the economy without credit score heterogeneity. Monetary policy in this economy affects household consumption through two channels. First is the wealth effect: the cut in interest rate decreases return on wealth for all agents and makes short-term borrowing cheaper for higher credit score borrowers. Second, the interest rate cut provides higher credit score households with the refinancing option, allowing to reset their mortgage rate to a lower one, which frees up disposable income for more consumption. Since higher credit score borrowers have lower MPCs than borrowers in a baseline economy with no credit score heterogeneity, the rate cut results in a dampened consumption response.

Even though distributional issues are outside central banks' mandates, recent research provided evidence that wealth and income inequality affect the effectiveness of monetary policy. We show that the same rate cut stimulates aggregate consumption less in an economy with a higher proportion of the borrowers with low credit score and limited access to credit markets.

Our paper contributes to contemporary mortgage research in three significant ways. First, we extend the existing literature on the mortgage market in monetary policy implementation by quantifying monetary policy transmission to the FRM refinancing using loan-level data. Second, we shed light on a novel source of heterogeneity of monetary policy transmission - credit score - that inhibits the smooth functioning of this channel. Finally, we identify refinancing heterogeneity by individuals with different credit scores and thus different MPCs, thus contributing to the newly emerging literature strand that highlights the redistribution effects of monetary policy.

A vast empirical literature stressed the importance of the mortgage market as a principal channel through which monetary policy affects the economy. The first papers in this strand of literature evaluated monetary policy transmission to households through adjustable-rate mortgages that are exposed to interest rate changes directly (see [Bhutta and Keys \(2016\)](#), and [DiMaggio, Kermani, Keys, Piskorski, Ramcharan, Seru, and Yao \(2017\)](#)). The most recent research studies the FRM market because 30-year FRMs are the dominant type of mortgage contract in the U.S. housing (see [Berger, Milbradt, Tourre, and Vavra \(2021\)](#), [DiMaggio, Kermani, and Palmer \(2020\)](#), [Beraja, Fuster, Hurst, and Vavra \(2018\)](#), and [Eichenbaum, Rebelo, and Wong \(2022\)](#)). In this paper, we further extend the existing literature by estimating the effect of monetary policy on the refinancing of 30-year FRMs with loan-level panel data.

One can divide the literature on the heterogeneity of monetary policy transmission

through the mortgage markets into two strands – one that examines demand-side consideration and the other that focuses on supply side constraints. On the empirical front, our main contribution is to show that credit score heterogeneity is significant and more important for aggregate refinancing than other loan characteristics, such as DTI and LTV ratios, that matter in the refinancing literature. On the theoretical front, we show that, given that credit scores determine borrowing constraints, this heterogeneity dampens the effect of monetary policy.

Many demand-side factors related to distribution of borrower characteristics matter for aggregate refinancing. For example, [Cloyne, Ferreira, and Surico \(2020\)](#) study how the distribution of renters vs. owners affects aggregate refinancing in the U.S. and the U.K. [Andersen, Campbell, Nielsen, and Ramadorai \(2020\)](#) show that refinancing is sub-optimal because of borrower inattention. [Gerardi, Willen, and Zhang \(2020\)](#) and [Wong \(2021\)](#) explore the role of demographic characteristics, such as race and borrower age, respectively. [Bhutta and Keys \(2016\)](#) document differential cash-out refinancing responses to changes in interest rate and house prices fluctuations during housing boom by credit score and borrower age. [Beraja, Fuster, Hurst, and Vavra \(2018\)](#) examine the effect of regional house price changes on the ability of households to refinance their mortgages. While we employ similar reduced form estimation, we focus only on rate refinancing, including the post-financial crisis period, and ignore refinancing due to house price changes that are indirectly affected by monetary policy.

Another strand of literature shows that, besides borrower characteristics, sub-optimal borrowing depends on supply-side factors, such as lender constraints. [Calza, Monacelli, and Stracca \(2013\)](#) show how the dominant type of contract (adjustable-rate vs. fixed-rate) affects refinancing in different countries. [Agarwal, Chomsisengphet, Mahoney, and Stroebel \(2018\)](#) show that even though marginal borrowing probability is higher for the lowest FICO credit score consumers, higher credit card limits resulting from credit expansion policies reduce profits from lending, leading to a decrease in aggregate credit card borrowing. [Greenwald \(2018\)](#) emphasizes the importance of LTV and DTI ratios for aggregate refinancing by studying the theoretical implications of the model with such frictions. In this paper, we focus only on FRMs, the dominant type of contract in the U.S. We control for DTI and LTV ratios and take care of the effects of changing underwriting criteria by including mortgage origination time fixed effects. We capture slowly moving lender concentration with fine time-by-geographic fixed effects.

Two papers that are closely related to ours are [Berger, Milbradt, Tourre, and Vavra](#)

(2021) and Eichenbaum, Rebelo, and Wong (2022). They have shown that refinancing rate incentives vary over time because FRM allows a borrower to *choose* whether they want to be exposed to a particular rate. While these papers focus on the effects of time-varying mortgage rate incentives on monetary policy, we show that even though some borrowers could benefit from refinancing, they remain locked in the previous rates because of difficulties in getting new loans. Credit score heterogeneity dampens monetary policy transmission to housing wealth compared to the scenario in which people with the most extensive benefits from refinancing can freely do so.

Finally, our paper is the first one to identify refinancing heterogeneity by individuals with different credit scores and different MPCs, thus contributing to the newly emerging strand of literature that highlights the redistribution effects of monetary policy. Theoretical work in this strand includes Hedlund, Karahan, Mitman, and Ozkan (2017), Kaplan, Moll, and Violante (2018), Auclert (2019), Kaplan, Mitman, and Violante (2020), Guren, Krishnamurthy, and McQuade (2021).

The structure of the paper is as follows. Section 2 describes the Fannie Mae Single-Family Loan-Level data we use in our empirical analysis. Section 3 documents empirical results on credit score heterogeneity. Section 4 outlines a refinancing model showing that credit score heterogeneity dampens housing wealth response to monetary policy. Section 5 concludes.

2 Data

To show that borrowers with lower credit scores are less likely to refinance in response to expansionary monetary policy we use Fannie Mae Single-Family Loan-Level historical dataset.⁵ Mortgages owned by Fannie Mae make up 26% of the total mortgage market, which, combined with other agency mortgage-backed securities, adds up to 61.3% of the mortgage market as of the first quarter of 2019. In May 2018, securities outstanding in the agency market totaled \$6.7 trillion, 42.8% of which was Fannie Mae (Goodman, McCargo, Golding, Parrott, Pardo, Hill, Kaul, Bai, Stochak, Reyes, and Walsh (2019)). This mortgage-level panel data contains information about loan-specific characteristics at the time of origination for fully amortizing, full documentation, single-family, conventional FRMs acquired by Fannie Mae. Each loan is tracked at a monthly frequency from the

⁵Retrieved from <http://www.fanniemae.com/portal/funding-the-market/data/loan-performance-data.html>.

month of origination until it is paid off voluntarily or involuntarily via the foreclosure process. Since each loan in the dataset has a unique identification number, implying that we cannot track the same borrowers over time, we treat each loan as belonging to a new borrower.

Our analysis includes loans originated in the January 2000 – March 2019 period. The data on loan performance extends through December 2021. In order to focus on a homogeneous mortgage product, we limit the sample to FRMs with a maturity of 30 years. 30-year FRMs make up over 60% of all mortgage contracts for our sample period.

Since our analysis is conducted on the monthly frequency where the unit of observation is a loan-month, we work with a 10 percent random sample of the Fannie Mae Single-Family data set to ease the computational burden. We construct our sample by selecting a 10 percent random sample of loans originated in each quarter during our sample period.⁶ The total number of FRMs is 3,580,928, resulting in 149,070,748 loan-month observations. In our analysis, we employ the remaining loan balance in each month from origination to prepayment and information on outstanding (fixed) interest rate, FICO credit score, debt-to-income ratio (DTI), loan-to-value ratio (LTV), loan purpose (cash-out refinance, rate refinance, purchase of a new house), and a 3-digit ZIP-code recorded at the time of mortgage origination.^{7,8}

We treat mortgages prepaid voluntarily before maturity (as opposed to involuntary prepayment via the foreclosure process) as refinanced and focus on total refinancing regardless of prepayment reason – rate decrease or equity extraction. [Berger, Milbradt, Tourre, and Vavra \(2021\)](#) have shown that rate incentives are a crucial driver of refinancing decisions, even for households taking cash out of their homes. To control for refinancing incentives arising from variation in home equity alone, we construct current LTV ratio for each loan in our sample using ZIP-level house prices from the Zillow database in two steps. First, we calculate the value of the mortgaged property at origination by dividing loan amount at the time of origination by the LTV at origination. Second, we divide remaining loan balance by the value of the mortgaged property at origination.

Table 1 displays summary statistics (minimum and maximum observations, means, medians, and standard deviations) for key observable variables in our sample. Panel A displays mortgage characteristics at origination from our data set where the unit of obser-

⁶We experimented with selecting a 10 percent random sample of all loans from the dataset, and all the results were statistically indistinguishable across these methodologies.

⁷In what follows, we use the terms "FICO credit score" and "credit score" interchangeably.

⁸Debt in DTI refers to the flow debt payment rather than a stock of debt.

vation is a loan (that is, one observation per loan), and Panel B displays summary statistics of the time-varying variables included in our analysis where the unit of observation is a loan-month (that is, multiple observations per loan).

We construct rate gap, $gap_{it} = m_i^* - \hat{m}_{it}$, by calculating the difference between the current fixed interest rate on the outstanding loan, m_i^* , and the predicted rate, \hat{m}_{it} , for a new FRM originated in period t given borrower/loan characteristics for FICO, LTV, and DTI at the time of origination from the following regression:

$$m_{it} = \alpha_0 + \alpha_1 CS_{it} + \alpha_2 CS_{it}^2 + \alpha_3 LTV_{it} + \alpha_4 LTV_{it}^2 + \alpha_5 DTI_{it} + \alpha_6 DTI_{it}^2 + \alpha_7 r_t^m + \varepsilon_{it} \quad (1)$$

where for each borrower i with loan originated in t , CS denotes a FICO credit score, LTV denotes loan-to-value ratio, DTI denotes debt-to-income ratio, and r_t^m denotes the 30-year FRM average in the U.S. from Primary Mortgage Market Survey (PMMS) by Freddie Mac.⁹

Table 2 displays estimation results of regression (1) and shows that coefficients are consistent with previous findings in the literature. Borrowers with higher credit score, lower LTV, and lower DTI ratio tend to have lower mortgage rates. This specification explains about 90 percent of variation in outstanding mortgage rates.

Although Fannie Mae has a minimum qualifying credit score of 620 and we focus only on conventional loans, we treat our sample as representative of the population of 30-year FRMs. Panel B of Table 1 shows that the average mortgage rate for contract in our sample (5.08) is close to the market 30-year FRM average (5.25). In Appendix A1 we show that the time series of mean mortgage rate for contracts in our sample is in line with the market 30-year FRM average. The average refinance rate is 1.53 percent per month which is comparable to 1.5 percent in Berger, Milbradt, Tourre, and Vavra (2021) for the period from 1992 to 2017.

Figure 1 plots Kaplan-Meier estimates of the unconditional average monthly rates of refinancing for lower (blue line) and upper (orange line) quartile credit score borrowers, with their 95% confidence bands, as a function of loan age.¹⁰ The unconditional refinancing rate for upper quartile credit score borrowers is up to 0.6 percentage points higher than those for lower quartile.

⁹Retrieved from FRED, Federal Reserve Bank of St. Louis at <https://fred.stlouisfed.org/series/MORTGAGE30US>.

¹⁰Loan age corresponds to number of months since mortgage origination.

3 Empirical Results

In this section, we show that the refinancing response to monetary policy depends on borrowers' credit score distribution. Our analysis comprises three steps. First, we provide visual evidence suggesting that credit score distribution affects refinancing and is a potential source of heterogeneity. Second, motivated by this observation, we find significant differences in refinancing across borrowers in different credit score quartiles. We start with plotting a prepayment hazard as a function of interest rate gap for different credit score groups. We then show that credit score heterogeneity is robust to controlling for the observable loan characteristics and fine geographic-by-time fixed effects. Next, we provide evidence that credit score heterogeneity is more important than that across other loan characteristics, such as debt-to-income (DTI) and loan-to-value (LTV) ratios. Third, we exploit exogenous changes in monetary policy to measure the marginal effect of credit score heterogeneity on refinancing to avoid bias caused by omitted variables that affect both mortgage rate and refinancing through channels distinct from monetary policy.

3.1 Credit Score Distribution as a Source of Heterogeneity

We present three pieces of visual evidence suggesting that refinancing depends on credit score distribution. The first shows that the unconditional refinancing rate is higher for borrowers with higher credit scores. The second illustrates rate and credit score dynamics for the borrowers in the same cohort and implies that borrowers with higher credit scores are the ones who refinance most actively. Third, we demonstrate that credit score distribution is time-varying. Time-varying credit score distribution implies that refinancing opportunities are state-dependent (in this case, the state is credit score distribution at each point in time).

In Figure 2, we plot unconditional monthly refinancing rate for lower (blue line) and upper (orange line) quartile credit score borrowers over our sample period. The figure suggests that during several episodes of loose monetary policy – quantitative easing QE1 and quantitative easing QE2, refinancing rate is higher for borrowers with higher credit scores.

Next, we turn to the single loan cohort dynamics and conclude that borrowers with a higher credit score are the ones who refinance most actively. In the top panel of Figure 3,

we plot the average mortgage rate of outstanding contracts originated in May 2000 and the current market mortgage rate. In the bottom panel of Figure 3, we plot the average credit score of outstanding contracts originated in May 2000. Market mortgage rate declined from 8.5% in 2000 to 3.8% in 2019. If the interest rate is the only determinant of refinancing, we would see average cohort rate falling over time because borrowers with the highest incentives to refinance would have prepaid their mortgages and left the sample. However, the average rate of outstanding loans in this cohort does not vary much, while their holders' average credit score is dropping, suggesting that borrowers with a higher credit score were more likely to refinance. Single cohort dynamics are similar for other cohorts – in Figure 4, we provide average mortgage rate and average credit score of outstanding contracts originated in May 2009.

To claim credit score state-dependence, besides the latter observations, one would also need to see the change in the borrowers' credit scores over time. Figure 5 suggests that it is indeed the case. Over the last 20 years, the average credit score of new borrowers in the lower quartile has increased by around 40 FICO points, whereas that of the borrowers in the upper quartile by only 20 points. Figure 6 confirms that time-varying credit score distribution is not an artifact of our sample – market credit score distribution from New York Fed Consumer Credit Panel and Equifax varies over time.

3.2 Heterogeneous Response of Refinance to Mortgage Rates

In this subsection, we show a substantial positive correlation between refinancing and credit score after controlling for rate gaps and other borrower characteristics. We do so by constructing refinancing hazards by rate gaps for each credit score quartile.

We start by looking at refinancing, pooling all monthly observations for contracts that were originated in 2000–2019. We then sort loan-months to 20 basis point wide gap bins and four credit score groups corresponding to quartiles of credit score distribution and estimate a non-parametric relationship between refinancing and rate gaps, credit score and their interaction using the following regression:

$$1\{\text{Refi}_{it}\} = \alpha + \beta_b 1\{\text{gap}_{it}^{\text{bin}}\} + \gamma_b 1\{\text{CS}_i^{\text{bin}}\} + \delta_b 1\{\text{gap}_{it}^{\text{bin}}\} \times 1\{\text{CS}_i^{\text{bin}}\} + X_{it}\Gamma + \eta_{ZIP} + \varepsilon_{it} \quad (2)$$

where $1\{\text{Refi}_{it}\}$ is a dummy variable equal to one if the loan was refinanced; $1\{\text{Refi}_{it}\}$ is a dummy for the gap bin of loan i in month t ; $1\{\text{CS}_i^{\text{bin}}\}$ is a dummy for the quartile bin of loan i in month t ; X_{it} is a vector of loan characteristics which includes a quadratic in LTV,

a quadratic in DTI, a quadratic in loan age, and dummy for whether the current loan was itself a new purchase, a cash-out refi or a rate refi, lagged ZIP-level house price; η_{ZIP} is a 3-digit ZIP-code fixed effects. Standard errors are two-way clustered by a 3-digit ZIP-code and month.

Figure 7 shows the resulting monthly refinancing hazard given by the point estimates for coefficients $\beta + \gamma + \delta$ for borrowers with credit score in lower (blue line) and upper (orange line) quartiles with their 95% confidence bands. Two observations stand out. First, there is a positive relationship between rate gaps and probability to refinance: loans with positive rate gaps are more likely to refinance than loans with the negative rate gap.¹¹ Second, positive-gap loans with FICO credit scores in the upper quartile have a 1 percentage point higher probability of refinancing for the same interest rate gap than loans with FICO scores in the lower quartile.

While higher credit score borrowers seem to have higher sensitivity of refinancing to rate gaps, it could be the case that higher credit score borrowers tend to have lower LTV ratios, higher income, and/or smaller mortgage balances. Figure 8 shows that restricting our sample to households with LTV ratio below 65% and excluding observations during 2007 – 2011 when households were more likely to be unemployed, does not change our results materially. Figure 9 suggests that our result is robust to restricting our sample to mortgages with outstanding balance above \$100,000 (mean of our sample). In Appendix A2, we show that our result is robust to aggregation to the quarterly level.

Results of this subsection imply that the refinancing differences between lower and upper credit score quartile borrowers with positive rate gaps is significantly large and robust to inclusion of other borrower characteristics, geographical fixed effects, loan duration and restricting sample to loans with substantial remaining balance.

3.3 Robustness

In this subsection, we show that the credit score heterogeneity in refinancing is significant and larger than that in other borrower characteristics – LTV, DTI, and remaining balance. We additionally demonstrate that it is robust to (i) using an alternative definition of rate gap aiming to remove borrower fixed effects, (ii) controlling for payment history rather than remaining balance, (iii) aggregation to quarterly frequency, and (iv) geographical aggregation. Finally, we show that this result is driven by the episodes of mortgage rate

¹¹Our results are in line with Berger, Milbradt, Tourre, and Vavra (2021).

decreases.

To establish that the credit score is the most important source of refinancing heterogeneity, we employ linear probability models and estimate them at a monthly frequency. Our regressions take the following form: for the loan i at month t , we estimate

$$1\{\text{Refi}_{it}\} = \alpha + \beta \text{gap}_{it} + \gamma \text{CS}_i + \delta \text{gap}_{it} \times \text{CS}_i + X_{it}\Gamma + \varepsilon_{it} \quad (3)$$

where $1\{\text{Refi}_{it}\}$ is a dummy variable equal to one if the loan was refinanced; gap_{it} is a rate gap of household i in month t ; CS_i is a credit score of household i ; $\text{CS}_i \times \text{gap}_{it}$ is the interaction between credit score and rate gap of household i in month t ; X_{it} denotes a vector of controls. In some specifications we include geographic fixed effects and origination year-month fixed effects. The standard errors are double clustered on 3-digit ZIP-code and month level. All variables except interest rate gap are normalised around corresponding sample means. All coefficients were multiplied by 100 to arrive to percentage changes.

Our specification controls for many observable variables that affect both refinancing and rate incentives. The main object of interest is the heterogeneity of refinancing response to monetary policy that affects market mortgage rates. Its extent is given by coefficients β in front of the rate gap and δ in front of the interaction between credit score and rate gap. This interaction captures the possibility that credit score which affects refinancing also varies with rate gaps. For example, borrowers with lower credit scores might be more likely to have both larger rate gaps and lower refinance probabilities.

We begin by quantifying credit score differences in the sensitivity of refinancing to gaps δ by running the OLS specification of equation (3). The estimation results are provided in Table 3.¹² Column (1) reports estimates from a specification without an interaction term, which includes a third-order polynomial for mortgage age (duration) and origination year-month fixed effects which take care of changes in underwriting criteria over time. The coefficients in front of rate gap and credit score are in line with previous findings of the literature on FRM channel. A 1 percentage point increase in rate gap is associated, on average, with a 0.84 percentage points higher probability to refinance. Borrowers with a 1 standard deviation above mean credit scores are 0.08

¹²Note that significance levels of 10%, 5%, and 1% in all of the tables were adjusted for the sample size. According to Leamer (1978), in very large samples we should reject the null if the test-statistic in absolute value is above $t_{cr} = \sqrt{N(N^{\frac{1}{N}} - 1)}$. Alternatively, one could adjust significance level according to the formula $\alpha_{stan} = \alpha / \sqrt{N/100}$.

percentage points more likely to refinance.

Recall that the rate gap is constructed using predicted rate for each borrower given their characteristics for FICO, OLV, and DTI. If differences in refinancing between lower and higher credit score borrowers are explained to their differential sensitivities to rate gaps, then coefficient before interaction term should be positive. This is confirmed in column (2) of Table 3, which shows that higher credit score borrowers are significantly more likely to refinance in response to rate gap increase. A 1 percentage point increase in rate gap is associated with a 1.2 percentage points increase in the probability to refinance for borrowers with credit score 800 (one standard deviation above mean credit score) but only a 0.64 percentage points increase for borrowers with credit score 700 (one standard deviation below mean credit score).

To determine whether differential sensitivities to rate gap between lower and higher credit score borrowers arise due to variation in their observable characteristics, in column (3) of Table 3 we include underwriting characteristics and state fixed effects. Underwriting characteristics include LTV, DTI, remaining balance, number of borrowers, indicators for whether the current loan was itself a new purchase loan, a cash-out refinancing or a rate refinancing, indicator for property type (condominium, co-operative, planned urban development, manufactured home, or single-family home), and occupancy status (principal, second, investor, unknown). Borrowers with lower LTV ratios and larger remaining balances are more likely to refinance. The sensitivity to rate gap remains significant and slightly increases. The coefficient on front of DTI has a positive sign suggesting that borrowers with higher DTI ratio are more likely to refinance.

In column (4) of Table 3 we estimate differential sensitivities to rate gap between lower and higher credit score borrowers using variation within 3-digit ZIP-codes. While ZIP-code fixed effects take care of time-invariant unobserved characteristics of small geographic areas such as demographics and average education level, they do not materially change estimates of either of the coefficients.

Finally, column (5) of Table 3 contains a full set of year-month-by-ZIP fixed effects. The inclusion of year-month fixed effects means that identification occurs entirely from ZIP-code variation rather than aggregate time-series variation within month.¹³ This eliminates concerns that results might be driven by endogenous monetary policy since monetary policy does not vary across regions. Moreover, the year-month-by-ZIP-code

¹³For example, controls for the year 2003 will take care of a large spike in refinancing in 2003 documented by [Justiniano, Primiceri, and Tambalotti \(2022\)](#).

fixed effects fixed effects guarantee that identification comes from ZIP-code-specific monthly variation within month and not from time-invariant regional differences. This eliminates concerns that results might be driven by differences in demographics, lender concentration or any other slower moving local characteristics. Controlling for these fixed effects decreases sensitivities to rate gap between lower and higher credit score borrowers by a fifth in absolute magnitude, from 0.3 to 0.24. Note that it also makes the coefficient in front of DTI insignificant. Comparison of columns (2) and (5) suggests that inclusion of all observable characteristics and time-by-location fixed effects decreases sensitivities to rate gap between lower and higher credit score borrowers only by 9% in absolute magnitude, from 0.27 to 0.24.

3.3.1 Other Sources of Heterogeneity

In this subsection, we test whether there is heterogeneity of refinance to rate gap across other borrower characteristics by including additional interactions to our main specifications. It might be the case that these factors that affect refinancing also vary with rate gaps similarly to credit score. For example, borrowers with lower credit scores, higher DTI ratios or higher LTV ratios might be more likely to have both larger rate gaps and lower refinance probabilities.

Column (1) of Table 4 corresponds to specification in column (5) in Table 3, which includes all controls as well as origination year-month and a full set of year-month-by-ZIP fixed effects. In column (2) of Table 4 we add interaction of rate gap with LTV ratio. The addition of this interaction does not materially change our estimate for the rate gap sensitivity between different credit score borrowers. Its sign is positive but small in magnitude. One possible reason for unintuitive sign is that borrowers with higher LTV ratios and large rate gaps are also the ones with higher remaining balances. This specification omits interaction of gap with remaining balance and leads to an upward bias of the coefficient.

In column (3) of Table 4 we add interaction of rate gap with the DTI ratio. Its sign is negative but small in magnitude suggesting that borrowers with DTI ratio of 45% (one standard deviation above mean DTI) are 0.04 percentage points less likely to refinance than borrowers with DTI ratio of 35% (one standard deviation below mean DTI).

In column (4) of Table 4 we add interaction of rate gap with the remaining balance. Interestingly, interaction of gap with LTV becomes insignificant (and negative). Loans with higher remaining balances are both more likely to refinance and more responsive to

interest rates – the interaction between gap and remaining balance essentially captures savings from refinancing. This finding is consistent with the mechanism proposed in Wong (2021).

Overall, results from Table 4 suggest that inclusion of these additional interactions have not affected significance of the credit score interaction and only slightly changed its magnitude, from 0.24 to 0.21. We conclude that credit score heterogeneity has economically significant effects on refinancing.

3.3.2 Alternative Measure of Rate Gap

Since we cannot track same borrowers over time, we construct an alternative measure of rate gap that has a lower measurement error due to borrower fixed effects. In this subsection, we show that our main result is robust to using this measure.

We construct rate gap, $gap_{it} = \hat{m}_{i\tau} - \hat{m}_{it}$, by calculating the difference between the predicted fixed interest rate on the outstanding loan, $\hat{m}_{i\tau}$, and the predicted rate, \hat{m}_{it} , for a new FRM originated in period t given borrower/loan characteristics for FICO, LTV, and DTI. Both rates are predictions from the regression (1), and $\hat{m}_{i\tau}$ is a prediction for a rate at the time of origination. The rationale behind this definition is to eliminate borrower fixed effects: for example, it could be the case that some borrowers get an unusually high or low interest rates for reasons unrelated with underwriting criteria.

The estimation results are provided in Table 5. Column (1) reports estimates from a specification without an interaction term, which includes a third-order polynomial for mortgage age (duration) and origination year-month fixed effects which take care of changes in underwriting criteria over time. The coefficients in front of rate gap and credit score are higher than those reported for the baseline model in Table 3. A 1 percentage point increase in this definition of rate gap is associated, on average, with a 1.26 percentage points higher probability to refinance. Borrowers with a 1 standard deviation above mean credit scores are 0.12 percentage points more likely to refinance.

Column (2) of Table 5 shows that a 1 percentage point increase in rate gap is associated with a 1.6 percentage points increase in the probability to refinance for borrowers with credit score 800 but only a 1 percentage point increase for borrowers with credit score 700. Column (3) of Table 5 includes underwriting characteristics and 3-digit ZIP fixed effects. While the credit score sensitivity to rate gap is higher than one from Table 3 (0.297 vs. 0.238), the relative difference between borrowers with excellent and good credit scores is smaller because this measure of rate gap has larger effect on refinancing. A 1

percentage point increase in rate gap is associated with a 1.74 percentage points increase in the probability to refinance for borrowers with credit score 800 and a 1.15 percentage point increase for borrowers with credit score 700.

3.3.3 Payment History

Even though FICO credit score of a borrower is persistent, FICO score at the moment when a borrower thinks of refinancing is more relevant for obtaining the refinance loan, rather than at mortgage origination. One of the most important determinants of FICO score is payment history. While we do not observe repayment of other debts except that of mortgage, in this subsection we examine credit score heterogeneity while controlling for change in the remaining balance, rather than absolute value of remaining balance.

The estimation results are provided in Table 6. Column (1) suggests that a 1 percentage point increase in rate gap is associated with a 0.88 percentage points increase in the probability to refinance for borrowers with credit score 800 and a 0.43 percentage point increase for borrowers with credit score 700. Inclusion of other interaction terms in column (2) does not significantly alter the results. Overall, the results from this estimation suggest the same relative difference between excellent and good credit score borrowers.

3.3.4 Time- and Geographical Aggregation

The micro-level evidence thus far shows a strong relationship between rate gaps, credit score sensitivity to rate gap and refinancing when pooling the data across all months and all individuals. We next show that our main result is robust to aggregation to quarterly frequency and 3-digit ZIP-code level.

Table 7 is the quarterly version of Table 7. The key difference between the two is that the interest rate gaps, LTV, remaining balance, and the refinance indicator are averaged quarterly (as opposed to monthly) for each borrower in our sample. All specifications include age control – third order polynomial for the number of quarters since origination and origination year-quarter fixed effects. Column (1) estimates imply that a 1 percentage point increase in rate gap is associated with a 2.1 percentage points increase in the quarterly probability to refinance for borrowers with credit score 800 (one standard deviation above mean credit score) but only a 1.13 percentage points increase for borrowers with credit score 700 (one standard deviation below mean credit score). In column (2) we include underwriting characteristics and ZIP-code fixed effects, and again find that the

refinancing differences between different credit score borrowers are more correlated with credit score rather than neighborhoods that these borrowers live in. Addition of a full set of year-quarter-by-ZIP-code fixed effects in column (3) only slightly decreases credit score sensitivity to rate gap, from 0.49 to 0.44 in absolute magnitude.

In Table 8 we exploit variation in rate gaps, credit score, and refinancing across ZIP-codes to show that there is a strong positive relationship between rate gaps, credit score sensitivity to rate gap and refinancing, even after including both year-month and year-month-by-ZIP-code fixed effects. Results are very similar in magnitude to ones obtained using loan-level variation. The specification with a full set of controls in column (3) implies that the credit score sensitivity to rate gap is 0.20, which is close to its loan-level counterpart of 0.24 from column (5) of Table 3.

3.3.5 Tightening Monetary Policy

Market mortgage rates have been mostly decreasing over the last 20 years. To show that expansionary and tightening monetary policy have asymmetric effects, in this subsection we re-estimate equation (3) during two episodes of tight monetary policy – from July 2004 to June 2006 and from December 2015 to December 2018.

Table 9 provides estimation results for two episodes of tightening monetary policy. Column (1) implies that credit score heterogeneity did not matter from July 2004 to June 2006. This result is consistent with Amromin, Bhutta, and Keys (2020) who document that borrowers with lower credit scores were more likely to refinance their mortgage to extract cash against increasing house equity caused by rising house prices.

Column (2) of Table 9 suggests that credit score heterogeneity was significant during December 2015 – December 2018 tightening cycle. Both rate gap and credit score sensitivity to rate gap are lower than for the whole sample period. A 1 percentage point increase is associated with 0.41 percentage point increase in refinancing probability for the borrower with a mean FICO score of 750. The marginal effect of increasing credit score by one standard deviation is 0.08 percentage points.

3.4 Causal Effect of Rate Gaps on Refinancing

Our finding that refinance response to mortgage rates is heterogeneous across borrowers with different credit score has important implications for monetary policy. Expansionary monetary policy increases rate gaps. Given that the relationship between rate gaps

and refinancing is causal, resulting increase in refinancing will be much higher among higher credit score borrowers than lower credit score borrowers. While the results in the previous subsections indicate a strong relationship between rate gaps and refinancing, it is possible that some unobserved confounding factor affects both rate gaps and refinance propensities even at monthly frequencies. For example, if household liquidity constraints are negatively correlated with rate gap and refinancing (during expansions, gaps are higher, and people are less liquidity constrained and more able to refinance), then OLS estimate of β and δ has a downward bias. In this subsection, we employ instrumental variable approach to estimate effects of monetary policy on refinancing probability.

We re-estimate equation (3) using a monetary policy shock as an instrument for interest rate gap and interaction of the shock with credit score as an instrument for the interaction of the rate gap with credit score. This approach exploits exogenous variation of rate gaps and leaves out variation due to unobserved confounding factors.

We construct two measures of monetary policy shocks using high frequency identification approach which are based on Federal funds futures rates, Eurodollar futures rates and Treasury yields. High-frequency identification controls for the market expectations by considering changes in the target rate within a small window and, thus, overcomes two empirical challenges in identifying the effect of monetary policy. The first is that movements in the target rate exhibit both the independent effects of monetary policy and shifts in demand for risk-free assets because Fed conducts policy endogenously in response to economic events that affect interest rates in the economy. The second is that markets may expect Fed's future actions because Fed officials could signal upcoming rate changes. Thus, when the Fed officially changes the target Federal funds rate, other rates may have already moved in expectation, which may appear as if Fed policy had no effect.

To obtain the first measure of monetary shocks, we closely adhere to the methodology of Swanson (2021), which is an extension of Gürkaynak, Sack, and Swanson (2005), by considering the change in the policy indicator in a 1-day window around scheduled FOMC announcements. The policy indicators we employ are the first three principal components of the unanticipated change over the 1-day windows from January 2000 to June 2019 in the following five interest rates: changes in Federal funds rates futures for the current month, changes in Federal funds rates futures for the month of the next FOMC meeting, eurodollars futures contracts at horizons of 2, 3, and 4 quarters, and 2-, 5-, and 10-year Treasury yields. The daily data is from the Bloomberg terminal. The dates and times of FOMC meetings up to 2004 are from the appendix to Gürkaynak, Sack, and

Swanson (2005) and the dates of the remaining FOMC meetings are from Nakamura and Steinsson (2018) and Swanson (2021).

In line with Swanson (2021), we interpret the three estimated factors as (i) the surprise component of the change in the federal funds rate at each FOMC meeting, (ii) the surprise component of the change in forward guidance, and (iii) the surprise component of any LSAP announcements. The sign of the first factor is such that it has a positive effect on the current federal funds rate, the second factor has a positive effect on the four quarter-ahead Eurodollar future contract, and the third factor has a negative effect on the 10-year Treasury yield. This way an increase in the first two factors corresponds to a monetary tightening, whereas an increase in the third factor corresponds to easing.¹⁴ Each factor is normalized to have a unit standard deviation. For all the details on high-frequency shock construction see Appendix A3.

The second measure of monetary shock is defined as the change in the 2-year Treasury yield in a 1-day window around scheduled FOMC announcements.

We begin by providing evidence that both shocks are plausible instruments for the mortgage rate gap. Table 10 provides first-stage regression estimates for each of the instruments, with Panel A corresponding to the first measure of monetary policy shock, and Panel B corresponding to the second measure. In both cases, we reject the null hypothesis of underidentification based on Kleibergen-Paap rk LM statistic for robust errors. We also reject the null of weak instruments based on Kleibergen-Paap Wald rk F statistic.

Point estimates in Panel A of Table 10 suggest that forward guidance and LSAP factors have larger effects on the mortgage rate as compared to federal funds rate. A 1 percentage point increase in the current federal funds rate target leads to 19 basis points decrease in the rate gap. A 1 percentage point increase in the expected federal funds rate one year ahead leads to 85 basis points decrease in the rate gap. Finally, a \$215 billion surprise LSAP announcement leads to 2.66 basis points increase in the rate gap.¹⁵

Point estimates in Panel B of of Table 10 imply that a 1 percentage point monetary

¹⁴The goal was to leave interpretation of the third factor as a purchase (LSAP) rather than sale of assets.

¹⁵Coefficients in Panel A of Table 10 are in basis points per standard deviation change in the policy instrument. The standard deviation of the fed funds rate factor is 8.39 basis points, of forward guidance is 5.68 basis points, and that of LSAP around \$215 billion (which corresponds to a roughly 15 basis point decline in the 10-year Treasury yield). See Swanson (2021) for details. Therefore, to compute effects of a 1 percentage point change in the current federal funds rate target, one needs to multiply coefficient by $100\text{bp}/8.39\text{bp} \approx 11.92$. To compute effects of a 1 percentage point change in the expected federal funds rate one year ahead, one needs to multiply coefficient by $100\text{bp}/5.68\text{bp} \approx 17.61$.

policy shock increases the rate gap by 56 basis points. Overall, estimates for both instruments are consistent with those from [Eichenbaum, Rebelo, and Wong \(2022\)](#) and [Gertler and Karadi \(2015\)](#).

Table 11 displays the results from estimating equation (3) separately using OLS and IV approaches with two different instruments described above. All these specifications include age controls and a full set of origination-year-quarter-by-ZIP-code fixed effects. Standard errors are double clustered by 3-digit ZIP-code and origination year-quarter. We start by outlining results for the model without underwriting characteristics in columns (1), (3), and (5). Both instrumental variable specifications yield similar results in absolute magnitude and confirm that OLS estimates for coefficients of gap and interaction of gap with credit score have downward bias. The estimate of sensitivity to rate gap changes from 0.21 to 0.39 when using instrumental variable approach. In columns (2), (4), and (6) we add underwriting characteristics. The addition of these controls slightly decreases IV estimates for the gap sensitivity from 0.39 to 0.37 for the first instrument, and from 0.39 to 0.36 for the second one. However, these estimates remain highly significant and around 1.5 higher than OLS counterpart in absolute magnitude.

Both IV specifications suggest that credit score heterogeneity has economically significant effects on refinancing. Column (3) suggests that the marginal impact of a one standard deviation increase in credit score is 0.37 percent, which amounts to 27% of the average monthly refinancing rate of 1.35 percent.¹⁶ Another way to see it is as follows. Assume that all independent variables in regression are equal to their sample averages and that average credit score is initially equal to its mean of 750. The unconditional average share of mortgages that refinance is equal to 1.35 percent. The estimates of coefficient β imply that a 100 basis point decrease in mortgage rate (corresponding to increase in rate gap) increases the share of refinanced loans to 2.435 percent.¹⁷ If a 100 basis point decrease in mortgage rate occurs when the average credit score is one standard deviation above mean, the share of refinanced loans rises to 2.803 percent.¹⁸ Therefore, the marginal impact of a one standard deviation increase in credit score is 0.368 percent. Similarly, the estimates in column (6) imply the marginal impact of a one standard deviation increase in credit score of 0.356 percent.

Results of this section imply that while expansionary monetary policy increases

¹⁶The average refinancing rate for the sample of FOMC months is slightly lower compared to the whole sample of 1.53% from Table 1.

¹⁷ $1.35 + 1 \times \hat{\beta} = 2.435$.

¹⁸ $1.35 + 1 \times \hat{\beta} + 1 \times \hat{\gamma} + 1 \times 1 \times \hat{\delta} = 2.803$. Note that the estimate for γ is not significant.

refinancing propensities for all borrowers, it disproportionately affects borrowers with higher credit scores. A 1 percentage point increase in rate gap increases the probability to refinance by 1.45 percentage points for borrowers with credit score 800 (one standard deviation above mean credit score) but only 0.72 percentage points for borrowers with credit score 700 (one standard deviation below mean credit score). Therefore, in response to monetary expansion, refinancing probability increases 2 times ($1.45/0.72$) more for borrowers with a FICO credit score of 800 compared to borrowers with a FICO score of 700.

4 Model of Refinance

Since we do not observe borrowers' spending and wealth, we develop a FRM refinancing model to show that credit score heterogeneity matters for monetary transmission to aggregate consumption.

Our continuous-time open economy model closely resembles a continuous-time open economy framework employed by [Berger, Milbradt, Tourre, and Vavra \(2021\)](#). Households are subject to idiosyncratic labor income risk and choose to consume or save in a liquid asset subject to a borrowing constraint, as in [Aiyagari \(1994\)](#). All households hold a FRM and are subject to aggregate interest rate risk. The mortgage rate in this model is a deterministic function of liquid short-term interest rate. Refinancing enters via a Calvo-style exogenous shock – households refinance at Poisson arrival times only if their rate gap is positive.¹⁹

The novel feature of our model is the means by which it integrates credit score heterogeneity: we assume that households' Calvo refinancing rates and liquid wealth borrowing limits correlate with their credit scores. We calibrate the probability of arrival of these refinancing shocks and borrowing limits to match the observed refinance rates and credit card limits by different credit score groups.

Our analysis focuses on comparing the effect of monetary policy on refinancing,

¹⁹Note that [Berger, Milbradt, Tourre, and Vavra \(2021\)](#) models endogenous relationship between short and mortgage rates. We abstract from redistribution between borrowers and lenders and focus on partial equilibrium outcomes for two reasons. First, lenders have much lower marginal propensities to consume as compared to borrowers, significantly decreasing the impact of their returns on aggregate outcomes. Second, in our setting, such model would generate a counter-factual relationship between mortgage rate and refinancing: lower credit score borrowers would receive lower mortgage rates. Instead, we assume that mortgage rates do not depend on credit scores to highlight the effect of credit scores beyond mortgage rates.

average coupons, and consumption in the environments without and with credit score heterogeneity. We conclude that credit score heterogeneity dampens the effects of monetary policy by 11%.

4.1 Uncertainty

Household i receives non-insurable idiosyncratic labor income Y_{it} per unit of time, with $\ln Y_{it}$ following the continuous time Ornstein-Uhlenbeck process:

$$d\ln Y_{it} = -\eta_y(\ln Y_{it} - \ln \bar{Y})dt + \sigma_y dZ_{it} \quad (4)$$

where Z_{it} is a standard Brownian motion that is independent across households and aggregate states of the economy given by short rate fluctuations, $\ln \bar{Y}$ is the ergodic mean of log income, σ_y^2 is the instantaneous variance (per unit of time) of log income, and η_y is the mean reversion parameter.

Households face aggregate uncertainty because short-term interest rate follows a stochastic process. We model these interest rates using [Cox, Ingersoll, and Ross \(1985\)](#) model of interest rate:

$$dr_t = -\eta_r(r_t - \bar{r})dt + \sigma_r \sqrt{\bar{r}} dZ_t \quad (5)$$

where Z_t is a standard Brownian motion, μ is the ergodic mean short-term rate, $r_t \sigma_r^2$ is the instantaneous variance per unit of time, and η_r is the mean reversion parameter.

Mortgage market interest rate m_t is the deterministic linear function of short-term interest rate r_t , so that fluctuations in $m_t = m(r_t)$ arise from fluctuations in r_t in equilibrium.

4.2 Household Balance Sheet and Refinancing

Each household is born at $t = 0$ with liquid savings W_0 and a house financed with a fixed-rate mortgage with constant balance F and coupon rate m_t^* . We assume that mortgages are never paid down to focus only on rate incentives for refinancing and abstract from cash-out refinancing. Even though refinancing incentives arising from house price movements are important, interest rates and resulting rate incentives respond almost immediately to monetary policy while house prices are indirectly and more slowly affected by monetary policy.

Each mortgage can be refinanced at the discretion of household only at random, exponentially distributed attention times. When these opportunities arise, the household can choose to keep its existing mortgage or to refinance at the current mortgage market rate m_t for free. This setup corresponds to a Calvo model in which households obtain opportunities to refinance at no cost at Poisson arrival times, and they exercise their option if and only if the current market interest rate m_t is below their outstanding coupon rate m_t^* .

Households can save or borrow in a liquid savings account W_t with return r_t to insure against labor income shocks. Thus, their liability is their outstanding mortgage, and payments on unsecured short-term debt if $W_t < 0$. Their net financial position is equal $W_t + r_t W_t 1\{W_t < 0\} - F$. Households do not have any option to default.

Credit score enters our model via differential arrival rates for refinancing shock and differential borrowing limits. Intuitively, credit score is a prediction of how likely household is to pay a loan back. If this probability is low, households cannot refinance mortgage and borrow more unsecured debt.

In the benchmark model without credit score heterogeneity, arrival intensity of refinancing shock χ and borrowing limit $b < 0$ is the same for all households. In the model with credit score heterogeneity, each household is born with (exogenous) credit score j which determines a Poisson arrival rate of χ_j of refinancing shock and borrowing limit b_j . There are no other differences between different credit score households.

Finally, we also assume that households face exogenous moving shocks that arrive at Poisson rate ν , forcing them reset their mortgage coupon to the current market mortgage rate m_t . This shock does not differ across different credit score borrowers.

Summary. The goal of our model is to provide a simple framework for analyzing the refinancing channel of monetary policy transmission in the presence of heterogeneity. Our partial equilibrium model has four state variables (W_i, r, m_i^*, Y_i) . Liquid wealth W and stochastic income Y introduce uninsurable income risk and wealth heterogeneity. Outstanding mortgage rate m^* introduces a refinancing motive. Time-varying interest rates r provides a role for monetary policy.

4.3 Household Problem

Households with identical constant relative risk aversion preferences with rate of time preference δ and intertemporal rate of substitution $1/\gamma$ make consumption $\{C_t\}_{t \geq 0}$ and

refinancing decisions $\{\rho_t\}_{t \geq 0}$ by solving the following problem:

$$\max_{C, \rho} E_0 \left[\int_0^\infty e^{-\delta t} \frac{C_t^{1-\gamma}}{1-\gamma} dt \right]$$

subject to

$$dW_t = (Y_t - C_t + r_t W_t - m_t^* F) dt, \quad W_t \geq b_j \quad (6)$$

$$dm_t^* = (m_t - m_{t-}^*) \left[\rho_t dN_t^{(\tau_{refi})} + dN_t^{(\tau_{move})} \right] \quad (7)$$

and Y_t following (4), r_t following (5), and $m_t = \alpha_0 + \alpha_1 r_t$. Here τ_{refi} is the sequence of times when refinancing shock arrives, τ_{move} is the sequence of times the household is forced to move, and $N_t^{(\tau_{refi})}$ and $N_t^{(\tau_{move})}$ are changes in the corresponding counting processes.

Appendix A4 provides Hamilton-Jacobi-Bellman and Kolmogorov Forward equations. We solve the model numerically using the finite difference method.

4.4 Calibration

In this subsection we describe the model's calibrated parameters. These parameter choices are summarized in Table 12.

Our calibration of the income process follows Floden and Lindé (2001), who estimate mean reversion parameter $\eta_y = 9.3$ percent (corresponding to a half-life of 7.3 years), conditional volatility $\sigma_y = 21$ percent, and an ergodic mean log income of $E[Y_t] = \$69,560$ per year, consistent with average US household income in 2019.

We view r_t as a short-term interest rate, and assume that the monetary authority adjusts these short rates. We estimate the mean reversion and volatility of rate process with maximum likelihood estimation using daily data for 3-month treasury yields from 2000 to 2019, and obtain $\eta_r = 28$ percent (corresponding to a half-life of 2.48 years) and $\sigma_r = 7$ percent. Given η_r and σ_r , we then set the ergodic mean of the process to $\bar{r} = 4.1$ percent so that the corresponding initial model implied mortgage rate at the mean is equal to its empirical counterpart in 2019 when we start our experiments. See Appendix A5 for details on GMM estimation.

We calibrate the linear function parameters, α_0 and α_1 , that relate market mortgage rates and short-term rates by regressing mean mortgage rate on 3-month treasury yields

from 2000 to 2019.

We set the coefficient of relative risk aversion γ equal to 2, which is a standard calibration in the consumption-savings literature. We fix the mortgage balance F to the average in our data of \$225,230.

Discount parameter δ is calibrated to match median wealth (excluding home equity) of homeowners in 2019 from Survey of Income and Program Participation (SIPP) data. Main homeowners for our sample period are Millennials, Generation X and Baby Boomers. We weight their wealth according to house purchase shares from "2021 National Association of Realtors Home Buyer and Seller Generational Trends." to arrive to a median wealth of \$48,362. This strategy requires $\delta=9$ percent per annum, and generates an ergodic average liquid savings $E[W_t]= \$ 90,391$.

We calibrate the annual moving rate ν to 8.4 percent to match the empirical refinancing hazard for mortgages with negative rate gaps. In the baseline model without credit score heterogeneity, we set $\chi=27$ percent, which implies an average monthly refinancing frequency from 2000 to 2019 of 2 percent. We set borrowing limit for this economy b to \$30,000 corresponding to average average credit card limit in 2019, according to Experian.²⁰

In the model with credit score heterogeneity, we assume that credit score j takes three values $j \in \{L, M, H\}$. We limit the model to three credit score groups – low, middle, and high – which occur with equal probability. We set $\chi_L = 0$ percent, restricting households from the lowest credit score group from refinancing. $\chi_M = 26.54$ percent, matching average refinancing rate for borrowers with positive rate gaps and FICO score below 75th percentile in our data. We set $\chi_H = 54.49$ percent, so that average refinancing rates are the same in baseline and heterogeneous economies.

We calibrate borrowing limits in the heterogeneous economy in the following way. We assume that low credit score households cannot borrow and set $b_L = 0$, medium credit score borrowers can borrow up to \$15,000, implying $b_M = -\$15,000$. Finally, to make the average borrowing limit equal between baseline and heterogeneous economies, we set $b_H = -\$45,000$.²¹

²⁰According to Experian, the average credit card limit in 2019 was \$31,459. Altering limit from \$30,000 to \$31,459 does not change our results.

²¹It is common to calibrate the credit card borrowing limit to one third of permanent income. For example, Kaplan, Moll, and Violante (2018) calibrate a borrowing limit of one times quarterly labor income. This number is consistent with reported credit card borrowing limits in the Survey of Consumer Finances.

4.5 Steady State

The steady state in our setup features cross-sectional heterogeneity in three variables: W , m^* , and Y . Figure 11 plots the steady state consumption function for a baseline economy with no credit score heterogeneity. From left to right, each panel represents a different income state. Consumption is decreasing in outstanding mortgage rate and decreasing in wealth. In Figures 12, 13, and 14, we provide steady state consumption functions for each credit score group, which are qualitatively in line with the baseline setup.

Table 13 summarizes the model's steady state. The first row lists average consumption. Average consumption is comparable across two economies, and is less than average income due to debt repayment. The second row lists average MPC out of liquid wealth. The baseline economy features average MPC of 0.33, and the heterogeneous economy - that of 0.37. Households in the low credit score group have highest MPCs with an average of 0.47, whereas these numbers are 0.36 and 0.27 for medium and high credit score groups. The final two rows summarize the accumulation of liquid wealth. In the baseline economy, 2.3% of households are at their borrowing limit. In the heterogeneous economy, this number is 2.4%. In the baseline economy more borrowers hold credit card debt as compared to the heterogeneous economy (6.3% vs. 5.4%).

4.6 Monetary Policy

Next we study the impact of stimulative monetary policy in economy with and without credit score heterogeneity. Starting from the steady state, interest rates are cut from 4.1% to 1.7% corresponding to 1% decline in market mortgage rate.

The top row of Figure 15 shows the impulse response functions (IRFs) of mortgage rate and average coupon in the baseline economy and economy with credit score heterogeneity. Mortgage rate is a linear function of interest rate and is the same for two economies by construction. Average coupon responds to monetary policy more strongly in the baseline economy. This is because the heterogeneous economy includes households who cannot refinance and, therefore, do not reset their mortgage rates.

The bottom row Figure 15 shows the IRFs of refinancing rate and consumption in the baseline economy and economy with credit score heterogeneity. Average refinancing rates in the two economies are calibrated to be the same, resulting in an almost identical on-impact response of refinancing. However, initial refinancing impulse declines faster in heterogeneous economy because refinancing shock arrives only to medium and

high credit score groups, and exhausts the number of households with both ability and incentives to refinance.

Even though differences in refinancing are not large, consumption responds more to rate cuts in the baseline economy than in the heterogeneous economy. On impact the aggregate spending semi-elasticity is 140 bps in the baseline economy versus 125 bps in the heterogeneous economy, i.e. a 11 percent increase over the baseline.

Heterogeneous economy is less responsive to monetary policy because low credit score households, who cannot borrow and refinance, have highest marginal propensities to consume. To show that low credit score group has significantly lower consumption response than other groups, in Figure 16 we decompose refinancing and consumption response by credit score group. On impact, households in low credit score group increase their consumption by 101 bps, whereas medium and high credit score households respond much more – by 131 and 143 bps, i.e. by 30 percent and 42 percent more than low credit score households.

Overall, monetary policy in this economy affects household consumption through two channels. First, there is the standard wealth effect - the change in interest rate r_t affects the household's return on W_t . This wealth effect includes only substitution effect, and no income effect, since we abstract from effect of monetary policy on income in this setup. Intertemporal substitution effect of rate cut induces household to save less (or borrow more) and increase their demand for consumption. Second, the interest rate cut gives some households the option to refinance and reset their mortgage rate into a lower one, which frees up disposable income for more consumption.

To decompose the initial consumption response to monetary policy into its two components and see how credit score heterogeneity affects each, we isolate the wealth effect, by shutting refinancing down in both economies. This decomposition is displayed in Table 14. Each cell in the first row represents the on-impact consumption elasticity in the model without refinancing. In homogeneous economy, 15% of total consumption response can be attributed to the refinancing channel. In heterogeneous economy, where households have differential borrowing constraints, only 10% of total response is through the refinancing channel. The refinancing channel in low credit score group is 0 by construction, so increase in consumption for this group is driven by wealth effect only.

Credit score heterogeneity dampens both wealth and refinancing channels because medium and high credit score have lower MPCs than low credit score borrowers. First, the differential borrowing limits affect wealth channel of monetary transmission. The

wealth effect is higher for medium and high credit score households compared to that for low credit score households. At the same time, the overall wealth effect is lower in the heterogeneous economy. This is because medium and high credit score households are able to borrow. Second, refinancing effect benefits higher credit score households by less than medium credit score households.

5 Conclusion

We have shown that credit score heterogeneity in the refinancing probability dampens monetary policy transmission through FRMs. Using Fannie Mae Single-Family Loan-Level historical data, we found that the effect of monetary policy on refinancing is heterogeneous across the credit constraints faced by the borrowers. In particular, a 1% expansionary monetary policy shock causes a 1.09pp average increase in probability to refinance, with one standard deviation increase in the credit score corresponding to a 0.37pp rise in the refinancing probability. Our refinancing model implies that the credit score heterogeneity dampens the consumption response to monetary policy by 11% – refinance gains increase by less for borrowers with higher chances of refinancing. Credit score heterogeneity is another significant source of monetary policy heterogeneity besides mortgage rate heterogeneity.

If the mortgage rate heterogeneity reflects the difference in refinancing gains, credit score heterogeneity implies differences in borrowing constraints. Our findings shed light on the monetary policy efficiency.

Figure 1: Smoothed Kaplan-Meier Unconditional Refinance Rates

Notes: Figure shows the smoothed Kaplan-Meier hazard estimates of refinance broken down by FICO score quartiles and the corresponding 95% pointwise confidence bands. The Kaplan-Meier estimate of the hazard function is: $\lambda(t_j) = \frac{d_j}{n_j}$, where d_j is the number of mortgage terminations due to refinance at time t_j , and n_j is the number of loans that have reached time t_j without being terminated or censored. The smoothed hazard-function estimator was calculated using the Epanechnikov kernel and the optimal bandwidth. Figure uses the Fannie-Mae Single-Family Loan-Level historical dataset.

Figure 2: Unconditional Monthly Refinance Hazard for Lower and Upper Quartile Credit Score Borrowers

Notes: Figure shows monthly refinance hazard defined as the monthly fraction of loans that refinance. Events are QE1, announcement of original LSAP in November 2008; QE2, Bernanke’s August 2010 speech suggesting an expansion of LSAPs; QE3, FOMC vote to buy \$40b bonds per month in September 2012; Taper tantrum, Bernanke’s 2013 FOMC press conference suggesting that FOMC would wind down purchases of MBS. The data come from the Fannie-Mae Single-Family Loan-Level historical dataset.

Figure 3: Outstanding and Current Market Mortgage Rates (top panel) and Average Credit Score of Outstanding Mortgages (bottom panel) on Mortgages Originated in 05/2000

Notes: Figure shows the average outstanding mortgage rate along with market mortgage rate (top panel) and average credit score (bottom panel) on mortgages originated in May 2000. Data on the average mortgage rate and average credit score on mortgages originated in May 2000 comes from the Fannie-Mae Single-Family Loan-Level historical dataset. The market mortgage rate comes from FRED, Federal Reserve Bank of St. Louis at <https://fred.stlouisfed.org/series/MORTGAGE30US>.

Figure 4: Outstanding and Current Market Mortgage Rates (top panel) and Average Credit Score of Outstanding Mortgages (bottom panel) on Mortgages Originated in 05/2009

Notes: Figure shows the average outstanding mortgage rate along with market mortgage rate (top panel) and average credit score (bottom panel) on mortgages originated in May 2009. Data on the average mortgage rate and average credit score on mortgages originated in May 2009 comes from the Fannie-Mae Single-Family Loan-Level historical dataset. The market mortgage rate comes from FRED, Federal Reserve Bank of St. Louis at <https://fred.stlouisfed.org/series/MORTGAGE30US>.

Figure 5: Credit Score at Origination for Lower and Upper Quartile Credit Score Borrowers

Notes: Figure shows the credit score at origination month (averaged across new borrowers) for borrowers in the lower and upper credit score quartile using the Fannie-Mae Single-Family Loan-Level historical dataset.

Figure 6: Distribution of Credit Score at Origination from New York Fed Consumer Credit Panel/Equifax

Notes: Figure shows the credit score at origination (averaged across new borrowers) for borrowers in 10th, 25th, and 50-th percentiles using data from New York Fed Consumer Credit Panel/Equifax

Figure 7: Refinance Hazard with Individual Controls for Lower and Upper Quartile Credit Score Borrowers

Notes: Figure shows point estimates for coefficients $\beta + \gamma + \delta$ on the 20bp bin dummies in regression (2) for borrowers in the lower credit score quartile (blue) and in the upper credit score quartile (orange). The estimation is performed at the monthly frequency on a 10% random sample of loans from the Fannie-Mae Single-Family Loan-Level historical dataset. The unit of observation is a loan-month. Controls include a quadratic in LTV, a quadratic in DTI, a quadratic in loan age, indicators for whether the current loan was itself a new purchase loan, a cash-out refinancing or a rate refinancing, and a 3-digit ZIP-code fixed effects. Standard errors are double clustered by 3-digit ZIP-code and year-month.

Figure 8: Refinance Hazard with Individual Controls: Low LTV Households

Notes: Figure shows point estimates for coefficients $\beta + \gamma + \delta$ on the 20bp bin dummies in regression (2) for borrowers with LTV < 65% in the lower credit score quartile (blue) and in the upper credit score quartile (orange). The estimation is performed at the monthly frequency on a 10% random sample of loans from the Fannie-Mae Single-Family Loan-Level historical dataset. The figure excludes data from the years 2007 to 2011. The unit of observation is a loan-month. Controls include a quadratic in LTV, a quadratic in DTI, a quadratic in loan age, indicators for whether the current loan was itself a new purchase loan, a cash-out refinancing or a rate refinancing, and a 3-digit ZIP-code fixed effects. Standard errors are double clustered by 3-digit ZIP-code and year-month.

Figure 9: Refinance Hazard with Individual Controls for Mortgages with Mortgage Balances > \$100,000 (top panel) and Mortgages with Mortgage Balances < \$100,000 (bottom panel)

Notes: Figure shows point estimates for coefficients $\beta + \gamma + \delta$ on the 20bp bin dummies in regression (2) for borrowers with balances more than \$100,000 (top panel) and balances more than \$100,000 (bottom panel) in the lower credit score quartile (blue) and in the upper credit score quartile (orange). The estimation is performed at the monthly frequency on a 10% random sample of loans from the Fannie-Mae Single-Family Loan-Level historical dataset. The unit of observation is a loan-month. Controls include a quadratic in LTV, a quadratic in DTI, a quadratic in loan age, indicators for whether the current loan was itself a new purchase loan, a cash-out refinancing or a rate refinancing, and a 3-digit ZIP-code fixed effects. Standard errors are double clustered by 3-digit ZIP-code and year-month.

Figure 10: Difference in Mortgage Rates of Lower and Upper Quartile Credit Score Borrowers

Notes: Figure displays the difference between the average mortgage rate paid by a lower versus an upper quartile credit score borrower. "New mortgages" are mortgages originated in the month. "Outstanding mortgages" are all mortgages outstanding in the month, including new mortgages. The data come from the Fannie-Mae Single-Family Loan-Level historical dataset.

Figure 11: Steady State Consumption Function in the Baseline Economy

Notes: Figure displays steady state consumption as a function over income, outstanding mortgage rate, and liquid wealth. See text for details.

Figure 12: Steady State Consumption Function for Low Credit Score Households

Notes: Figure displays steady state consumption as a function over income, outstanding mortgage rate, and liquid wealth for low credit score households. See text for details.

Figure 13: Steady State Consumption Function for Medium Credit Score Households

Notes: Figure displays steady state consumption as a function over income, outstanding mortgage rate, and liquid wealth for medium credit score households. See text for details.

Figure 14: Steady State Consumption Function for High Credit Score Households

Notes: Figure displays steady state consumption as a function over income, outstanding mortgage rate, and liquid wealth for high credit score households. See text for details.

Figure 15: Refinancing and Consumption Response to Monetary Policy

Notes: Figure displays the IRF of mortgage rate, outstanding coupon, refinancing rate, and consumption C to a 240 basis point decline in short-term interest rate r .

Figure 16: Refinancing and Consumption Response to Monetary Policy in Heterogeneous Economy

Notes: Figure displays the IRF of refinancing rate and consumption C to a 240 basis point decline in short-term interest rate r for each credit score group.

Table 1: Summary Statistics of the Fannie Mae Data

| Panel A: Fixed Characteristics at Mortgage Origination | | | | | |
|---|-------------|--------|----------|--------|--------|
| | Median | Mean | St. Dev. | Min | Max |
| Interest Rate (ppts) | 4.75 | 4.90 | 1.39 | 1.88 | 12.13 |
| Loan Amount (\$100k) | 2.00 | 2.26 | 0.13 | 0.01 | 15.66 |
| LTV (%) | 79.00 | 73.89 | 16.31 | 1.00 | 97.00 |
| DTI (%) | 35.00 | 34.53 | 10.85 | 1.00 | 64.00 |
| FICO Credit Score | 757.00 | 746.92 | 48.05 | 620.00 | 850.00 |
| Refinance Loan | 1.00 | 0.54 | 0.50 | 0.00 | 1.00 |
| Purchase Loan | 0.00 | 0.46 | 0.50 | 0.00 | 1.00 |
| Rate Refinance Loan | 0.00 | 0.30 | 0.46 | 0.00 | 1.00 |
| Cash-out Refinance Loan | 0.00 | 0.24 | 0.43 | 0.00 | 1.00 |
| Number of loans | 3,580,928 | | | | |
| Panel B: Time-Varying Characteristics | | | | | |
| | Median | Mean | St. Dev. | Min | Max |
| Loan Age (months) | 31.00 | 42.31 | 39.07 | 1.00 | 263.00 |
| Interest Rate (ppts) | 5.00 | 5.08 | 1.19 | 1.88 | 12.13 |
| Remaining Balance (\$100k) | 1.59 | 1.85 | 1.10 | 0.00 | 15.66 |
| LTV (%) | 65.77 | 64.38 | 21.83 | 0.00 | 156.31 |
| Refinance (ppts) | 0.00 | 1.53 | 12.29 | 0.00 | 100.00 |
| Number of loan-months | 149,070,748 | | | | |

Notes: Table shows summary statistics from a 10% random sample of fully amortizing, full documentation, single-family, conventional 30-year FRM acquired by Fannie Mae between January 1, 2000 and March 31, 2019. The unit of observation in Panel A is a loan, while the unit of observation in Panel B is loan-month. Refinance Loan, Purchase Loan, Rate Refinance Loan, Cash-out Refinance Loan, and Refinance are dummy variables.

Notes: Table reports LPM estimates of loan-level regression (3) – the likelihood of mortgage refinance on a set of mortgage characteristics. The estimation is performed at the monthly frequency on a 10% random sample of loans from the Fannie-Mae Single-Family Loan-Level historical dataset. The unit of observation is a loan-month. All variables, except the rate gap, were standardized around mean. Refinance indicator was multiplied by 100 to arrive to percentage changes. Underwriting characteristics include LTV, DTI, remaining balance, number of borrowers, indicators for whether the current loan was itself a new purchase loan, a cash-out refinancing or a rate refinancing, indicator for property type (condominium, co-operative, planned urban development, manufactured home, or single-family home), and occupancy status (principal, second, investor, unknown). All 50 columns include age controls – 3rd order polynomial for the number of months since origination (duration). Standard errors are double clustered by 3-digit ZIP-code and origination year-month.

Notes: Table reports LPM estimates of loan-level regression (3) with additional interaction terms – the likelihood of mortgage refinance on a set of mortgage characteristics. The estimation is performed at the monthly frequency on a 10% random sample of loans from the Fannie-Mae Single-Family Loan-Level historical dataset. The unit of observation is a loan-month. All variables, except the rate gap, were standardized around mean. Refinance indicator was multiplied by 100 to arrive to percentage changes. Underwriting characteristics include LTV, DTI, remaining balance, number of borrowers, indicators for whether the current loan was itself a new purchase loan, a cash-out refinancing or a rate refinancing, indicator for property type (condominium, co-operative, planned urban development, manufactured home, or single-family home), and occupancy status (principal, second, investor, unknown). All columns include age controls – 3rd order polynomial for the number of months since origination (duration). Standard errors are double clustered by 3-digit ZIP-code and origination year-month.

Notes: Table reports first-stage from instrumental variable estimation of loan-level regression (3). In Panel A instruments for gap are 3-factors from PCA of eight interest rate changes around FOMC announcement days, and instruments for gap × CS are corresponding interactions of 3 factors with credit score. Coefficients are in basis points per standard deviation change in the policy instrument. In Panel B the instrument for gap is the change in 2-year Treasury yield around FOMC announcement, and the instrument for gap × CS is the corresponding interaction of shock with credit score. Coefficients are in percentage points. The estimation is performed at the monthly frequency on a 10% random sample of loans from the Fannie-Mae Single-Family Loan-Level historical dataset. The unit of observation is a loan-month. All specifications include age controls, a full set of underwriting characteristics, and a full set of origination year-quarter-by-ZIP-code fixed effects. Standard errors are double clustered by 3-digit ZIP-code and origination year-quarter.

Table 11: OLS and IV Results Refinance Probabilities for Regression (3)

Notes: Table reports OLS and IV LPM estimates of loan-level regression (3). See text for details on instruments. The estimation is performed at the monthly frequency on a 10% random sample of loans from the Fannie-Mae Single-Family Loan-Level historical dataset. The unit of observation is a loan-month. All variables, except the rate gap, were standardized around mean. Refinance indicator was multiplied by 100 to arrive to percentage changes. Underwriting characteristics include LTV, DTI, remaining balance, number of borrowers, indicators for whether the current loan was itself a

Table 12: Model Parameter Values

| Parameter | Value | Description | Target or Source |
|---|-------------|--|--|
| Exogenous Parameters | | | |
| <i>Income</i> | | | |
| $\ln 2/\eta_Y$ | 7.35 years | half-life of (log) income shock | Floden and Lindé (2001) |
| σ_Y | 21% p.a. | (log) income volatility | Floden and Lindé (2001) |
| $E[Y_t]$ | \$69,560 | (unconditional) income mean | US household average in 2019 |
| <i>Interest Rate</i> | | | |
| $\ln 2/\eta_r$ | 2.48 years | half-life of interest rate shock | 3-month Treasury yields |
| σ | 7.0% p.a. | interest rate volatility | 3-month Treasury yields |
| \bar{r} | 4.1% p.a. | (unconditional) interest rate mean | mean mortgage rate 3.91% in 2019 |
| <i>Mortgage Rate</i> | | | |
| α_0 | 2.33% | constant term of mortgage rate function | regression of mortgage rate on 3-month Treasury yields |
| α_1 | 0.43% | slope of mortgage rate function | regression of mortgage rate on 3-month Treasury yields |
| <i>Other Structural Parameters</i> | | | |
| γ | 2 | risk aversion | literature |
| δ | 8.65% p.a. | household discount rate | median wealth of \$48,362 weighted average of wealth (excluding home equity) medians for Millennials, Generation X, Baby Boomers |
| F | \$225,230 | mortgage balance | average in data |
| Refinance and Borrowing Parameters | | | |
| ν | 8.4% p.a. | arrival rate of moving shock | refinance rate for $gap < 0$ in data |
| χ | 27% p.a. | arrival rate of refinance shock | refinance rate for $gap > 0$ in data |
| χ_L | 0% p.a. | shock arrival rate for low credit score group | assumption |
| χ_M | 26.54% p.a. | shock arrival rate for medium credit score group | refinance rate for $gap > 0$, FICO < 75 th percentile |
| χ_H | 54.49% p.a. | shock arrival rate for high credit score group | χ in baseline economy, given χ_L, χ_M |
| b | \$30,000 | borrowing limit | average credit card limit in 2019 |
| b_L | \$0 | assumption | |
| b_M | \$15,000 | assumption | |
| b_H | \$45,000 | b in baseline economy, given b_L, b_M | |

Table 13: Steady State Summary Statistics

| | Baseline Economy | Heterogeneous Economy | | | |
|-------------------------------------|------------------|-----------------------|--------|--------|--------|
| | | Low | Medium | High | Total |
| Average consumption (\$) | 63,955 | 63,550 | 64,173 | 64,224 | 63,982 |
| Average MPC out of wealth | 0.33 | 0.47 | 0.36 | 0.27 | 0.37 |
| Share of constrained households | 2.3% | 2.5% | 2.6% | 2.1% | 2.4% |
| Share of households with $W \leq 0$ | 6.3% | 2.5% | 4.7% | 9.1% | 5.4% |

Notes: This table summarizes household consumption, expenditure, and saving behavior in the steady state.

Table 14: Consumption Response Decomposition

| | Baseline Economy | Heterogeneous Economy | | | |
|---------------------|------------------|-----------------------|-----------|-----------|-----------|
| | | Low | Medium | High | Total |
| Wealth effect (bps) | 119 (85%) | 101 (100%) | 110 (84%) | 125 (87%) | 112 (90%) |
| Total effect (bps) | 140 | 101 | 131 | 143 | 125 |

Notes: This table decomposes the channels through which monetary policy produces a consumption response on impact. The first row presents the consumption elasticity when households are not allowed to refinance. The second row presents the consumption response in the full model. Parentheses indicate the share of the total consumption response.

Appendices

A1 Mortgage Sample Representativeness

We treat our sample as representative of the population - Figure A1 shows that the mean mortgage rate for contracts in our sample heels the monthly average of the Freddie Mac weekly PMMS survey 30-year FRM average.

Figure A1: Average Outstanding Rate in Fannie Mae Data vs. Market Mortgage Rate (FRED)

Notes: Figure shows the average outstanding mortgage rate of the Fannie-Mae Single-Family Loan-Level historical data and the market mortgage rate from FRED, Federal Reserve Bank of St. Louis at <https://fred.stlouisfed.org/series/MORTGAGE30US>.

A2 Additional Empirical Results

Figure A2 is the quarterly version of Figure 7 in the main text. The key difference between Figure 7 is that the interest rate gaps and refinance indicator are averaged quarterly (as opposed to monthly). A comparison between Figure 7 and Figure A2 shows that they are very similar. In particular, both show significant differences in refinance between lower and upper quartile credit score borrowers.

Figure A2: Robustness of Refinance Hazard to Quarterly Frequency for Lower and Upper Quartile Credit Score Borrowers

Notes: Figure shows point estimates for coefficients $\beta + \gamma + \delta$ on the 20bp bin dummies in regression (2) for borrowers in the lower credit score quartile (blue) and in the upper credit score quartile (orange). The estimation is performed at the quarterly frequency on a 10% random sample of loans from the Fannie-Mae Single-Family Loan-Level historical dataset. The unit of observation is a loan-quarter. Controls include a quadratic in LTV, a quadratic in DTI, a quadratic in loan age, indicators for whether the current loan was itself a new purchase loan, a cash-out refinancing or a rate refinancing, and a 3-digit ZIP-code fixed effects. Standard errors are double clustered by 3-digit ZIP-code and year-quarter.

Figure A3 is the annualized version of Figure 7 in the main text. The key difference between Figure 7 is that the interest rate gaps and refinance indicator are averaged annually (as opposed to monthly). Even annualized refinance hazards for lower and upper quartile credit score borrowers differ significantly for rate gaps below 2%. For higher rate gaps, hazard estimates become increasingly imprecise.

Figure A3: Robustness of Refinance Hazard to Annual Frequency for Lower and Upper Quartile Credit Score Borrowers

Notes: Figure shows point estimates for coefficients $\beta + \gamma + \delta$ on the 20bp bin dummies in regression (2) for borrowers in the lower credit score quartile (blue) and in the upper credit score quartile (orange). The estimation is performed at the annual frequency on a 10% random sample of loans from the Fannie-Mae Single-Family Loan-Level historical dataset. The unit of observation is a loan-year. Controls include a quadratic in LTV, a quadratic in DTI, a quadratic in loan age, indicators for whether the current loan was itself a new purchase loan, a cash-out refinancing or a rate refinancing, and a 3-digit ZIP-code fixed effects. Standard errors are double clustered by 3-digit ZIP-code and year.

A3 Construction of Monetary Policy Shocks

We use high-frequency measures of monetary policy shock. High-frequency identification controls for the market expectations by considering changes in the target rate within a small window and, thus, overcomes two empirical challenges in identifying the effect of monetary policy. The first is that movements in the target rate exhibit both the independent effects of monetary policy and shifts in demand for risk-free assets because Fed conducts policy endogenously in response to economic events that affect interest rates in the economy. The second is that markets may expect Fed's future actions because Fed officials could signal upcoming rate changes. Thus, when the Fed officially changes the target Federal funds rate, other rates may have already moved in expectation, which may appear as if Fed policy had no effect.

To obtain a measure of shocks, we closely adhere to the methodology of [Swanson \(2021\)](#) by considering the change in the policy indicator in a 1-day window around scheduled FOMC announcements. The policy indicators we employ are the first three principal components of the unanticipated change over the 1-day windows from January 2000 to March 2019 in the following five interest rates: changes in Federal funds rates futures for the current month, changes in Federal funds rates futures for the month of the next FOMC meeting, eurodollars futures contracts at horizons of 2, 3, and 4 quarters, and 2-, 5-, and 10-year Treasury yields.

We focus only on scheduled FOMC meetings as unscheduled meetings may occur in response to other contemporaneous shocks. The outliers in a few periods can disproportionately affect the estimation of shocks across all dates in the sample. To avoid this problem, we follow [Nakamura and Steinsson \(2018\)](#) and [Swanson \(2021\)](#) who omit the FOMC announcement on September 17, 2001, which took place before markets opened but after financial markets had been closed for several days following the 9/11 terrorist attacks.

We get the unanticipated changes in eight interest rates around FOMC meetings in two steps. First, we convert prices of all five futures to expected yields, in percentage points, by calculating $y_t = 100 - x_t$, where x_t is the quote price on the contract and y_t is the implied yield to maturity. Second, we difference all variables across a window around FOMC announcements.

We scale changes in the Fed funds futures to take into account FOMC announcement timing. Before an FOMC meeting, the anticipated yield at settlement for the Fed Funds

contract expiring in the current month ($ff1_{t-\Delta t}$) is a weighted average of the average Fed Funds rate prior to announcement (r_0) and the rate that is expected to hold for the remainder of the month (r_1):

$$ff1_{t-\Delta t} = \frac{d1}{D1} r_0 + \frac{D1-d1}{D1} E_{t-\Delta t}(r_1) + \rho1_{t-\Delta t}$$

where $d1$ is the day of the FOMC meeting, $D1$ is the number of days in the month and $\rho1$ denotes risk premium. Surprise component is the change in the federal funds rate target given by

$$mp1_t = (ff1_t - ff1_{t-\Delta t}) \frac{D1}{D1-d1}$$

As window is small, we assume that change in risk premium is zero. Same procedure is then applied to changes in fed funds target after the second FOMC meeting from now (r_2). $ff2$ is the fed funds futures rate for month containing the next FOMC meeting:

$$ff2_{t-\Delta t} = \frac{d2}{D2} E_{t-\Delta t}(r_1) + \frac{D2-d2}{D2} E_{t-\Delta t}(r_2) + \rho2_{t-\Delta t}$$

where $d2$ is the day of the next FOMC meeting, $D2$ is the number of days in the month of that meeting and $\rho2$ denotes risk premium. Change in expectations for the second meeting is then given by

$$mp2_t = \left[(ff2_t - ff2_{t-\Delta t}) - \frac{d2}{D2} mp1_t \right] \frac{D2}{D2-d2}$$

We collect these eight asset price responses into $T \times n^{22}$ matrix X , with rows corresponding to FOMC announcements and columns to different assets. We normalize each column of X to have zero mean and unit variance. As in Swanson (2021) and GSS (2005), we present these data in terms of a factor model,

$$X = F\Lambda + v \tag{A1}$$

where F is a $T \times 3$ matrix containing 3 unobserved factors, Λ is a 3×8 matrix of loadings of asset price responses on 3 factors, and v is a $T \times 8$ matrix of white noise residuals uncorrelated over time and across assets.

To estimate the unobserved factors F , we extract the first three principal components

²² $T = 171$ because there are 171 FOMC meetings from January 1, 1999 to July 1, 2019. $n = 8$ because we use eight asset price changes.

of X and rotate them to interpret as (i) the surprise component of the change in the federal funds rate at each FOMC meeting, (ii) the surprise component of the change in forward guidance, and (iii) the surprise component of any LSAP announcements. We impose the following identifying assumptions on the orthonormal rotation matrix. First, changes in forward guidance have no effect on the current federal funds rate. Second, changes in LSAPs have no effect on the current federal funds rate. Third, variance of LSAP factor is minimized in the pre-ZLB period corresponding to sample from January 1, 1999, to February 1, 2009.

We perform two normalization of the rotated factors. First, the sign of the first rotated column is such that it has a positive effect on the current federal funds rate, the second factor has a positive effect on the four quarter-ahead Eurodollar future contract ED4, and the third factor to have a negative effect on the 10-year Treasury yield. This way an increase in the first two factors corresponds to a monetary tightening, whereas an increase in the third factor corresponds to easing.²³ Second, we normalize each rotated factor to have a unit standard deviation, so the coefficients in all the regressions are in units of basis points per standard deviation change in the monetary policy instrument.

Table A1 reports the loading matrix implied by the identifying restrictions on the rotation matrix. Our results are broadly consistent with Swanson (2021) in signs and magnitude of coefficients although we use daily rate data and employ a shorter sample to identify monetary policy shocks.

A one-standard-deviation increase in the federal funds rate factor is estimated to raise the current federal funds rate by 11.2 basis points, the expected federal funds rate at the next FOMC meeting by about 8 basis points, the second, third and fourth Eurodollar futures rates by 6.7, 6.2, and 4.8 basis points respectively, and the 2-, 5-, and 10-year Treasury yields by about 0.04, 0.02, and 0.01 basis points respectively. We can see that the effects of a surprise change in the federal funds rate is largest at the short end of the yield curve and dies off monotonically as the maturity of the interest rate increases. This is in line with the results from [Gürkaynak, Sack, and Swanson \(2005\)](#), and [Swanson \(2021\)](#).

In the second row, the effect of forward guidance is completely different. The zero effect on the current federal funds rate is by construction. But, as we can see in the estimates from the expected federal funds rate onward, the effect of forward guidance has more of a hump shaped response, where it peaks at approximately the one year horizon and then diminishes at longer horizons. This hump shaped response is also consistent

²³The goal was to leave interpretation of the third factor as a purchase (LSAP) rather than sale of assets.

| | <i>mp1</i> | <i>mp2</i> | <i>ed2</i> | <i>ed3</i> | <i>ed4</i> | 2Y Tr. | 5Y Tr. | 10Y Tr. |
|------------------|------------|------------|------------|------------|------------|----------|----------|----------|
| Fed Funds Rate | 11.20*** | 8.10*** | 6.65*** | 6.23*** | 4.81*** | 0.04*** | 0.02*** | 0.01** |
| Forward Guidance | (0.24) | (0.18) | (0.38) | (0.15) | (0.32) | (0.00) | (0.00) | (0.00) |
| LSAP | 0.00 | 0.06 | 6.48*** | 8.02*** | 9.17*** | 0.06*** | 0.08*** | 0.06*** |
| | (0.18) | (0.13) | (0.27) | (0.11) | (0.23) | (0.00) | (0.00) | (0.00) |
| | 0.00 | 0.21 | 4.64*** | 4.45*** | 3.93*** | -0.02*** | -0.03*** | -0.03*** |
| | (0.16) | (0.12) | (0.25) | (0.10) | (0.21) | (0.00) | (0.00) | (0.00) |
| <i>N</i> | 171 | 171 | 171 | 171 | 171 | 171 | 171 | 171 |
| R^2_{adj} | 0.93 | 0.92 | 0.88 | 0.98 | 0.93 | 0.89 | 0.99 | 0.92 |

Standard errors in parentheses

* $p < 0.10$, ** $p < 0.05$, *** $p < 0.01$

Table A1: Coefficients in the table correspond to elements of the structural loading matrix, in basis points per standard deviation change in the monetary policy instrument. *mp1* and *mp2* denote the scaled changes in the first and the third federal funds futures contracts, *ed2*, *ed3*, and *ed4* denote changes in the second through fourth Eurodollar futures contracts; and 2Y, 5Y, and 10Y Tr. denote changes in 2-, 5-, and 10-year Treasury yields.

with [Gürkaynak, Sack, and Swanson \(2005\)](#), and [Swanson \(2021\)](#).

In the case of LSAPs in the third row, the effect on the current federal funds rate is zero by construction and a one standard deviation increase in LSAP causes the 2-, 5- and 10- year treasury yields to fall on average, consistent with [Swanson \(2021\)](#).

We conclude that our high-frequency measure of monetary policy shocks correspond pretty to changes in federal funds rate, forward guidance and LSAPs.

A4 Household Problem Solution

The system to be solved is characterized by Hamilton-Jacobi-Bellman equation (HJB) and Kolmogorov Forward equation (KFE). HJB equation corresponding to household value function $V(r, W, m^*, Y)$ is given by

$$\begin{aligned}
\delta V(W, r, m^*, Y) = & \max_C u(C(W, r, m^*, Y)) + \mathcal{L}_r V + \mathcal{L}_Y V \\
& + (v + \chi_j 1\{m(r) < m^*\}) [V(W, r, m(r), Y) - V(W, r, m^*, Y)] \\
& + (rW + Y - C(W, r, m^*, Y) - m^* F) \partial_W V
\end{aligned} \tag{A2}$$

where \mathcal{L}_r is the infinitesimal operator associated with the stochastic process r_t , \mathcal{L}_Y is the infinitesimal operator associated with the stochastic process Y_t .

A5 Calibration of Parameters for Short Term Interest Rate Process

The dynamics of the short term interest rate evolve according to the following stochastic differential equation:

$$dr_t = -\kappa(r_t - \mu)dt + \sigma\sqrt{r_t}dZ_t \quad (\text{A3})$$

We follow [Cox, Ingersoll and Ross \(2005\)](#) to estimate parameters of (A3) using the generalized method of moments (GMM). We apply Euler discretization to obtain

$$\begin{aligned} r_{t+1} &= \alpha + \beta r_t + \varepsilon_{t+1} \\ \varepsilon_{t+1} &= \sigma\sqrt{r_t}\sqrt{\Delta t}N(0, 1) \end{aligned} \quad (\text{A4})$$

where $\beta = -\kappa\Delta t$, $\alpha = \kappa\mu\Delta t$, and $N(0, 1)$ is a random shock with zero mean and unit variance. From (A4) it follows that

$$\begin{aligned} E[\varepsilon_{t+1}] &= 0 \\ E[\varepsilon_{t+1}^2] &= \sigma^2 r_t \end{aligned} \quad (\text{A5})$$

Using (A5) and orthogonality condition, we can derive four moment conditions such that $E[g(\kappa, \mu, \sigma)] = 0$:

$$g(\kappa, \mu, \sigma) = \begin{bmatrix} \varepsilon_{t+1} \\ \varepsilon_{t+1}r_t \\ \varepsilon_{t+1}^2 - \sigma^2 r_t \\ (\varepsilon_{t+1}^2 - \sigma^2 r_t)r_t \end{bmatrix}$$

The corresponding sample moments are given by

$$\hat{g}(\kappa, \mu, \sigma) = \frac{1}{T} \sum_{t=1}^T g(\kappa, \mu, \sigma)$$

where T is a number of observations. The GMM moment function is defined as

$$J = \hat{g}'(\kappa, \mu, \sigma)\hat{W}\hat{g}(\kappa, \mu, \sigma)$$

where \hat{W} is weighting matrix. Our parameter estimates are found by minimizing J with respect to κ, μ, σ .

This model is overidentified - we have four moment conditions and three parameters to estimate. We will estimate GMM in two stages. First, we minimize objective function using identity weighting matrix. We will use estimates from the first stage to get $\hat{W} = \hat{S}^{-1}$, where \hat{S} is an estimate of the spectral density matrix of population moment functions. We use Newey-West estimator of spectral density matrix

$$\hat{S} = \hat{S}_0 + \sum_{j=1}^k \left(1 - \frac{j}{k+1}\right) (\hat{S}_j + \hat{S}'_j)$$

where

$$\hat{S}_j = \frac{1}{T} \sum_{t=j+1}^T g_t(\kappa, \mu, \sigma) g'_{t-j}(\kappa, \mu, \sigma)$$

This choice of weighting matrix results in asymptotically efficient estimates.

For our estimation we use daily data for 3-month Treasury yields from 1992 to 2007. This yields $T = 4003$ observations. We set $dt = 1/250$ (daily data) and number of lags in spectral density decomposition $k = 12$ (so our estimates are close to MLE).
